When the history of the twentieth century has been written, it is doubtful if any accomplishment along the lines of preventive medicine will stand out more prominently than the medical inspection and examination of school children; inspection preeminent consideration of which is the prevention of disease; inspection which at school guards against contagion in every form and discovers the existence of physical defects that interfere with the child's development, school progress, educable capacity, equipment, and future usefulness; inspection which by a thorough "follow up" process in the home, unearths hidden and unsuspected contagion and stimulates in parents an endeavor to have physical defects remedied and thus prevent shattered and perverted lives and degenerate citizenship; inspection which is not only of and for to-day, but which will make the future homes a more potent environment for the development of the physical, mental, moral, and spiritual well being of their offspring; inspection which has for its ultimate goal the betterment of home conditions and the welfare of the child—"the nation's best asset," as he has been called.

The socioeconomical conditions of life in New York city are so complex, so different from those of almost any other city in the world, and so intimately interwoven with school life, that any attempt at accomplishing results from medical school inspection, however successful, will require only yearly successful, unless constant and repeated attention is given to the home. It is in the home that many conditions, which after persistent effort are eradicated or ameliorated by the nurse at school, are re-born, as it were, to renewed activity: it is in the home that hygienic, dietetic, and other errors must ultimately be corrected, and it is in the home that the peculiar customs and mode of living which have been brought to us by the alien population and which are pronounced and firmly rooted, must be combated, ere we hope to see light in the solution of many school problems. To appreciate the part which tradition, prejudice, and superstition play, one has only to accompany an inspector and...
nurse of the health department to the various home quarters to which their daily work carries them. Here you will be brought face to face with a motley crowd which may not "fit the age in which we live," but which must be reckoned with and approached in every instance from a different standpoint.

Come with me then into the heart of the tene-ment district and listen to the answers which are given to the inspectors and nurses in response to their plea for early and proper treatment of the physical defects found in the school children, and to their advice on prevention of contagion, on child diet, child care, hygiene, and sanitation. It is needless to state that defective eyesight in its many phases—near sightedness (myopia), far sighted-ness (hyperopia), astigmatism, etc.—is one of the most frequent causes of retardation at school. Truly with many of the children, to see or not to see is the question. And yet the answers which some parents give and the arguments which they advance in response to the request for eyeglasses and other forms of treatment would seem laughable were the problem not so serious. They will tell you that eyeglasses are a luxury, that they are worn for style, that they make the child look old, that the child will get used to them, that he or she will be subjected to ridicule at the hands of the play-mates—a frequent taunt being "Oh, you four eyes!" They add that the wearing of eyeglasses will become a habit, that the child will never be able to get along without them, and that the eyes will grow weaker. And after all this, the mother of the lower East Side—the Ghetto section—will tell you that the presence of eyeglasses will interfer-ere seriously with her daughter's matrimonial prospects, that she "won't marry well," or as one mother told me of her ten year old, "if she needs glasses let her husband buy them." It is, in fact, an open secret in this section of the city that the marriage marketable value of a daughter with eye-glasses is below par. Not infrequently when visit-ing the home of a child excluded from school for mucopurulent conjunctivitis you will find an infant or another child similarly affected and the mother attempting a cure by literally squirting breast milk into the eyes. What a woeful waste of nutrition! What an ideal culture medium for bacteria! And many mothers in order to prevent strabismus will continually keep passing their hands before the child's eyes, while the Bohemian element not in-frequently treats ulcer of the eyeball by dusting sugar into the child's eyes.

How many children of to-day owe their deafness to the fact that their parents considered "running ears" beneficial and to the belief that like "running sores" they allowed the "poison" to escape readily and thus purify the blood? I have often called the attention of parents to the fact that a child ex-perienced some difficulty in hearing which should be given immediate attention, only to be informed that "at home he hears too much."

With all that has been written, published, and preached on the subject, it would seem as if parents should realize the necessity and importance of free and unobstructed nasal passages. Nothing is more vital for the growth and development of a child's body and mind than oxygen. And with oxygen we might group sunlight—the arch enemy of the tubercle bacillus, organic matter, and humidity; for as the Italian proverb puts it, "Where the sun does not go the doctor does." The ill effects of en-larged tonsils and adenoids—the main causes of nasal obstruction in childhood—are constant, progres-sive, and accumulative, and are acting against the child all the time. These defects limit the proper ingress of air and therefore inhibit the pro cess of healthful tissue changes; they disturb sleep, cause restlessness and night terrors, interfere with the hearing, tend toward deformities of the jaw, render speech and voice defective, stunt growth and development, predispose toward pulmonary in-volvement and chest deformities, and interfere with what a school child requires most—his memory and retentive faculties. And yet when all this is explained, what do we hear from some parents?

The negro, with full assurance of his position, informs you knowing that her child's nasal twang is due to the fact that the "child's palate is down," and follows this enlightening statement with the advice that by constant pulling of the hair on the top of the child's scalp the palate will become elev-ated and the condition relieved.

One of Ireland's buxom daughters, when told of the enlargement of her child's tonsils, stated defiantly, "Is that so? Sure. God put them there, and there they'll stay." And in many cases they do—while you make a hasty exit.

The colored mother when approached upon the question of operation for these conditions frankly tells you, "The Lord made my child as He made me, and I ain't going to have no one trying to improve on His work." An educated negro, when advised to have his adenoids removed, indignantly replied, "The negro is in a great measure charac-terized by his flat nose, and yet you advocate the removal of my adenoids, which would result in making my nose higher. I shall never do it. Al-ways be what you are."

The mother of the Jewish ghetto offers as her excuse: "If the tonsils are taken out the throat will be too wide and air will rush into the lungs too quickly and produce inflammation of the chest." While another will tell you that removal of the tonsils will interfere with the speech and indeed with the singing voice, and again you will be told that removal of the tonsils and adenoids "produces a loss of sexual instinct and creative power" or that the patient will "become hypochondriacal and have suicidal tendencies."

Voodooism or the superstition of the negro finds its victims in the Northern cities as well as in the Southern states. I have come in personal relation with cases where the use of different colored yarn was applied by the "doctor" for the cure of contagious and other diseases found in school children—red yarn for erysipelas, yellow for jaundice, pink for "pink eye," and white for anemia. One inspec-tor when working in a school district frequented by negroes was much perplexed at the stubborn-ness of a large number of cases of ringworm only to learn that the best treatment was held to be the application of a round piece of cloth which the voodoo doctor carefully applied, mumbling dili-gently the while.
The Italian parent is firmly convinced that the unsightly crust of eczema so often seen on the scalp is a protective covering placed there by an all wise Providence and that to remove it would cause the death of the child. Even a suggestion that olive oil be applied—and olive oil according to the Italian mind is surely good for what ails you—is not over enthusiastically received and the appearance of an otherwise attractive little Angelina or Raffaello is marred.

Venture to tell the East Side mother to cut the child’s hair which is matted together by dirt, pediculosis capitis, or scalp disease, and note her horror at the thought of his growth being prevented, or of his strength going with it.

And who is so bold as to enter one of these homes and advise that the child’s nails be cut short. Cut them, so that he “will become a thief” or “have his speech retarded” will be the retort. Bite them off—yes! Cut them—never!

Comment adversely upon the Italian school child dressed in an array of garments of many sizes, shapes and colors, which may be pulled off, one after the other like the coats of an onion, and be told that if these precautions are taken in the fall he will be protected from the rigor of winter, the dangers of cold and the discomforts of low temperature. While in the home, argue with a mother of this nationality against the use of the swaddling clothes in which the infant is bound, and which impedes its freedom of motion, and interfere with its breathing and circulation, only to be assured that this mummylike garb will keep the legs straight and the feet small. Like the Chinese, the Italians believe that small feet are a distinct advantage for girls.

Fancy entering a home on the lower East Side—the Jewish quarter—for the purpose of instructing a mother in the care of the mouth and teeth, to be shown her toothless jaw and then to be told in significant jargon, “I haven’t any teeth either and I am alive. Continue your rounds in this section, meet a well nourished and well developed youngster, admire it, say nice things about it, be friendly with it, and then watch the mother hastily lick its eyes and face three times, expectorating as she does so. How else can she remove the “evil eye” which you have unknowingly cast upon it? And if she does not resort to this procedure, it is only because she has scared away this evil spirit by sewing some salt in the child’s shirt or by tying red ribbon around its wrist or neck.

The negress will tell you that pulling teeth gives the children sore eyes and that “it is bad luck for any poor child to have gold or silver in the mouth.” One mamy said, “I pulls my own chile’s teets, and they is mighty lucky if they kin git the holes stopped up wid meat and bread.”

Woe betide you if you chance to step over the child as it plays on the floor in his home! Doesn’t this retard its growth? Atone then for your mistake, retract your steps and recross it.

Time and again you will be told that the child has ringworm because he played in the circles which children so frequently chalk for games on the sidewalk.

You may be discounting upon the backwardness of the child in the school studies and its dependence upon some physical defect, only to be looked at by the mother in wonderment and told that “the child’s memory is weak because he persists in eating the ends of the bread loaves.” Or you may be instructing the mother that the cause of her child’s bed wetting is some nervous disturbance, some disease of the kidneys or bladder, or perhaps adenoids, only to see her shake her head significantly and in her compassion for your ignorance say, “The child always plays at the fire with matches before he goes to bed.”

Primary or essential malnutrition claims about three per cent. of the school children of New York city—some twenty to twenty-five thousand—and calls for instruction to the parents on proper housing, sleep, play, ventilation, personal and home cleanliness, and food of proper quality, quantity, selection, preparation, and palatability. It also means that such children are referred by the inspector and nurse to open air classes or country homes, that suitable school lunches are provided. and that the cooperation of the various social and relief agencies is obtained. But many mothers will tell you that their children are pale because they look into the looking glass late at night. Why does the nurse insist upon telling the mother that she must not give the child “a taste of everything”? Doesn’t this indiscriminate tasting harden the child? And doesn’t deprivation at this time mean that in after years the child will suffer from want, hunger, and unsatisfied desires? The Italian mother, whose child is suffering from poor nutrition, is with great difficulty persuaded to discontinue wine, beer, and coffee as of no nutritive value. These are considered as tonics and are used to “strengthen” the children.

I remember having had occasion to advise one mother as to the existence of adenoid vegetations and pigeon breast in her child, only to be told at the next visit of the following therapeutic measure for retarding further development of the chest deformity. The child was taken to the coffin of a religious individual, and the latter’s hand was rubbed several times over the pigeon breast, when presto, the deformity was supposed to decrease.

And after advising proper measures for the removal of warts and moles, I have been told that a small piece of meat stolen from a butcher and buried in the earth would cause the growth to shrivel up and disappear simultaneously with the disintegration of the buried meat.

What would you say of the theory of predigested foodstuffs if you saw a mother deliberately chewing bread, meat, or vegetables and then placing it in a spoon and giving it to the child?

Often you will find that your visit to a sick child is accepted with great satisfaction because of the belief that “each friendly visitor takes away onesixtieth part of the disease.”

Frequently enough you will observe that the mother calls her child to task for describing upon his body how a neighbor’s child was operated upon, fearing that because of this a similar operation will be performed upon him.

I remember one little Italian youngster who was always shy when I approached him, afraid it
seemed to me as if some one were about to do him bodily harm. Subsequently I learned that having red hair, he was looked upon as a 'bad character' and as such was beaten regularly—a therapeutic measure indicated according to the mother's interpretation.

Sobel is such of the difficulties with which the path of the inspectors and nurses of the Department of Health is strewn; such are the types which they meet, such the conditions which confront them daily, which call for tact, judgment, patience, perseverance, kindness, encouragement, and enthusiasm.

And thus you will see, as James Creelman puts it, that New York city is "a Niagara of conflicting bloods, tongues, religions, and civilizations, flowing together from all parts of the earth, and carrying with it the social and political prejudices and discouragements of older nations. London is English, Paris is French, Berlin is German, St. Petersburg is Russian, and Canton is Chinese. But who will say that New York, the largest municipal unit in the world, is American?"

To recognize a condition, to inform parents of its existence is one thing, but to have treatment instituted is another. So serious at one time did this question of parental cooperation become that it was suggested that legislation be enacted to compel parents to have these physical defects remedied.

It is questionable whether any such compulsory law will be enacted in our day, any that will stand the test of the courts, and I admire the courage of those who advocate the idea. With Kerley I prefer to say, "I do not believe in compulsion or in attempt at legislating righteousness into people. I do believe in education sufficient so that each individual may with reason and intelligence direct his life and habits." The easier way, that of education, I believe to be along the line of least resistance; "accomplishing mighty feats by gentle suasion" will prove in the long run not only more effective but more lasting.

Dr. Abraham Jacobi, in an address, said: "I have come to believe that the social betterment and the equalizing humanitarianism required in our country is better than the social revolution which I hoped for fifty or sixty years ago. I believe that more can be accomplished by organization, cooperation, and evolution than by more violent means. The lesson taught by the great men of science is that we should leave some vestiges of our creation, large and small, to live after us."

I present for your consideration four charts which show in a numerical way how a persistent follow up campaign in New York city has succeeded in routing the forces of prejudice, distrust, and superstition, and how as a result increased physical efficiency of school children has been attained.

Chart I shows that of the children examined during 1909 to 1912 the percentage of those requiring treatment for all physical defects declined from 74.48 in 1909 to 71.6 in 1912.

Chart II shows that of the children examined and requiring treatment for other defects than of teeth only the percentage has declined from 44.2 in 1909 to 30.1 in 1912, and that the percentage of children requiring treatment for teeth has declined from 57 in 1909 to 49.4 in 1912.

Chart III shows the educational results of medical inspection and examination of school children, in that the percentage of children with defective vision, defective nasal breathing, and hypertrophied tonsils has declined steadily from 1909 to 1912. This table also shows that all children considered, the percentage with defective teeth has declined from 57 in 1909 to 49.4 in 1912. Essential malnutrition, that is, malnutrition without any contributing physical defect, has remained almost stationary—3.14 in 1900 to 2.8 in 1912. These figures coupled with our experience that in children admitted to school for the first time the number of defects found is becoming smaller proves to my mind that the public is beginning to learn the lesson that the best time to take care of the child's health is before it enters school. The examinations during these years were conducted in similar groups of children, new admissions being examined first in all cases and examinations being made from grade to grade.

Chart IV shows how the public has been educated up to the necessity for the use of eyeglasses—twenty-seven per cent. in 1909 to 50.3 per cent. in 1912; and to the advisability and benefits of operations upon the nose and throat—from twenty-two per cent. in 1909 to twenty-eight per cent. in 1912. The decrease from 33.3 per cent. in 1909 to twenty-eight per cent. in 1912 was due to the inability of our nurses to take the children to hospitals and dispensaries as frequently as in former years, because...
of the institution of a system which placed the control of contagious diseases in their hands and which required the major part of their time at school.

New York city, because of the constant influx of immigration, has at all times a conglomerate army of alien population which must be taught. That this is feasible despite the aforementioned obstacles, that education does reach and has reached them, is testified to, by the fact that many parents have come to realize the importance of having the physical defects of their children treated or removed, and have done so in many instances before the child entered school life.

And it is common experience these days to find that the word operation for school children does not carry with it the terror of years ago. Time there was when to mention this word was to incite a panic not only at home but in the immediate school and neighborhood. To-day many parents have been educated up to the point where they realize that intervention of this nature is the only proper method of cure, and they signify their approval in many instances by permitting, yes requesting, the nurse to take the child to the clinic. To see one of these mothers, who a year ago shrank from the idea of operation, reason with and urge her neighbor to have the child operated upon, can be appreciated only by those who have watched the development of this work. Nor does the idea of oral hygiene and the care of the teeth meet with that indifference which was formerly so pronounced. Now we see the tooth brush and powder in many homes, albeit at times that one brush is called upon to do service for the entire family.

The present generation of mothers, largely foreigners, can be, and is being, educated but this education must of necessity proceed slowly and with difficulty. They are so imbued with fear, indifference, suspicion, tradition, prejudice and superstition that knowledge, up to a certain point only, will be absorbed. The vast majority of mothers are willing and anxious to keep their children well and will try to do so if approached in the proper manner. They must be taught to recognize the solemn duty which rests upon them, they must lead the way that their children may follow; they must learn in order that they may direct, and what they do not learn, the school boys and girls of to-day—the citizens and mothers of the morrow—will teach them. They will bring into the homes, by reason of superior advantages offered to them, that light, that knowledge which will cause fewer lives to be sacrificed upon the altar of doubt, ignorance and superstition. This is exemplified during every summer vacation by our organization of Little Mothers' Leagues and by the school children voluntarily presenting themselves to many of the clinics for diagnosis, treatment, or operation, so that they might obviate the possibility of treatment during the school term.

A kind word, an evident interest in the child, gentle suasion, explanation of the effects of the condition and the benefits of treatment, with special emphasis upon the fact that removal of the defect will increase the child's future wage earning capacity—a plain heart to heart talk in their native tongue—therein lies the hope of parental cooperation these days.

And this parental cooperation will come about in one way only. Just as a Prussian king once said: "Three things are necessary for war—money, money and more money," so in overcoming tradition, prejudice and superstition three things are necessary, "education, education and more education." Concentration of our energies upon the home, upon the mother, must be our byword if we ever hope to help the child.

Train ye a mother in the way she should go and when her children grow up they will not depart from it.

A QUANTITATIVE CHEMICAL REACTION FOR THE CONTROL OF POSITIVE WASSERMANN REACTIONS.

(Third Communication.)

By D. M. Kaplan, M. D.,
New York.
Director of Laboratories, The Neurological Institute.

AND J. E. McCLELLAND, A. B., M. D.,
New York.
Resident Physician, First Division, The Neurological Institute.

The results obtained in the quantitative chemical estimation of the alpha amino nitrogen of the aliphatic acid group in the blood serum have been so gratifying that a further report seems advisable. The chemistry of the reactions involved and the theoretical chemistry of the aliphatic amino groups explaining why the amount of amino nitrogen should be less in syphilitic than in nonsyphilitic sera have already been considered.1

The technic used in the cases now under consideration was identical with that formerly reported: 2.5 c. c. of blood serum were treated with twenty-five c. c. of ninety-five per cent, alcohol and allowed to stand over night at room temperature. This was then evaporated in a porcelain evaporating dish over a water bath at about 60° C., almost to dryness, but not entirely so. The residue was dissolved in boiling hot water (ten c. c.).

Care must be taken to secure every minute trace of the residue. This suspension contains, among other things, the amino nitrogen and is ready for the apparatus to determine the quantity present.

REAGENTS.

The evolution of the NO₂ gas was accomplished as before, by using ten c. c. of C. P. glacial acetic acid and forty c. c. of sodium nitrite (granular) solution (300 grammes of sodium nitrite in 1,000 c. c. water). A preliminary correction to determine the amount of unabsorbable gas present in the sodium nitrite solution was made every day when performing the test. For the absorption of the NO₂ gas an alkaline solution of potassium permanganate (fifty grammes of pure potassium permanganate and twenty-five grammes of potassium hydrate per litre) was used in an ordinary Hempel pipette.

DESCRIPTION OF THE APPARATUS.

The complexity of the Van Slyke apparatus makes lucid description difficult, but because so many inquiries have been made regarding it we

1 New York Medical Journal, June 7 and July 26, 1913.
shall again attempt this task. In the accompanying schematic diagram and photograph the barometer and thermometer are not shown. The type of apparatus in this communication corresponds to the latest model improved by Doctor van Slyke. It is driven by a motor with the exception of the Hempel pipette, which is shaken by hand. A is a compound cylinder consisting of three parts, a, b, and c. Parts a and c are graduated.

Into a are poured the reagents for the evolution of \( \text{NO}_2 \) gas in order to displace the air, as air is not absorbed by the alkaline permanganate solution. These solutions are permitted to run separately into b. The chamber b is connected by a one way stopcock 4 with chamber e, which receives the evaporated and dissolved solution to be tested. The two way stopcock 2 connects chamber b either with the waste or with burette D through the stopcock 3. The stopcock 3 also provides a connection between the burette D and the Hempel pipette E. F is the water reservoir, which connects with the bottom of burette D by means of a rubber tube, thus permitting of raising or lowering of the bulb in order to create positive or negative pressure in the burette D.

PREPARATION OF THE APPARATUS.

First fill the lower bulb of the Hempel pipette and one half of the upper bulb with the alkaline potassium permanganate solution; stopcocks 2 and 3 are turned so as to connect burette D with the waste. The water reservoir and the burette D are then filled with distilled water while holding the water bulb above the level of stopcock 2; stopcock 3 is closed and, after lowering the water bulb, is again turned so as to connect burette D with the Hempel pipette. This causes the permanganate solution from the Hempel pipette to flow into the burette D. As soon as a few tenths of a cubic centimetre have passed over into D the stopcock 3 is turned neutral and the water bulb is raised again above the level of stopcock 2, and the stopcock 3 turned so as to connect with the waste, in order to drive off the few tenths of permanganate from the burette D. This procedure establishes a continuous column of permanganate from the Hempel pipette to the burette D and after D has been cleared of permanganate and the stopcock turned neutral there is also established an uninterrupted column of water from the top of stopcock 3 to stopcock 2. After turning stopcock 3 neutral (having cleared the burette D of permanganate) the water bulb is again lowered. Stopcock 2 is turned so as to connect B with the waste; stopcocks 1, 4, and 5 are turned neutral. The apparatus is now ready for the driving off of the air in a.

TECHNIC OF DRIVING OFF THE AIR AND FILLING A WITH \( \text{NO}_2 \) GAS.

Ten c. c. of glacial acetic acid are poured into a and at once permitted to flow into b by turning stopcock 1. Stopcock 1 is again turned into the neutral position and forty c. c. of the sodium nitrite solution are poured into a; this is also permitted to run into b by opening the stopcock 1. The acetic acid and the sodium nitrite solution at once begin to evolve a brownish gas, which is the \( \text{NO}_2 \) necessary for the riddance of the air. The surplus \( \text{NO}_2 \) escapes through the waste. Turn the stopcock 2 so as to direct the column of gas against the water column in g instead of into the waste. With the stopcock 1 still open the motor is started and permitted to shake the contents in b until chamber a is about four fifths full of returned fluid: stop the motor and turn stopcock 1 neutral and immediately connect D with b by opening stopcock 3. This will force the column of water in D down and the apparatus is ready to receive the specimen to be analyzed. The previously dissolved evaporated alcoholic serum extract is poured into e and stopcock 4 opened to permit the fluid to run into b. Care must be exercised not to permit the least amount of air to enter the chamber b. The motor is started again and permitted to work for five minutes, no more nor less. This shakes the acetic acid, sodium nitrite and the suspension to be tested, causing the liberation of the nitrogen attached to the aliphatic amino acid group in the alpha position. The evolved gas lowers the column of water in D. At the end of five minutes the motor is stopped and after a lapse of one minute the fluid in a is permitted to flow into b by turning stopcock 1. This causes the fluid in b to drive the least quantity of nitrogen gas into burette D; care must be taken not to allow any fluid to run into D, as this may give wrong results when the fluid in D is driven back into the Hempel pipette. Having carefully transferred all the gas from A into D stopcock 3 is turned so as to exclude burette D from communication with A. Now turn stopcock 3 neutral and raise bulb F above the entire apparatus; if possible suspend the bulb from

![Fig. 1.—Schematic diagram of apparatus.](image-url)
a hook or some such support. Turn stopcock 3 so that it will establish a communication between D and the Hempel pipette E. The pressure from the water in the raised bulb will force the gas in the burette D into the permanganate solution in the Hempel pipette, where the gases, with the exception of the NH₃ nitrogen, are rapidly absorbed. In transferring the gases from the burette into the

Hempel pipette one must be careful not to transfer the gases too rapidly, as the permanganate solution may spurt out of the upper bulb of the Hempel pipette. It is therefore advisable during the gas transfer to shut the cock 3 occasionally, when the permanganate rises too high in the upper Hempel bulb, and to shake the pipette for a few seconds, which causes the rapid (almost instantaneous) absorption of the gas. Having transferred all the gas into the Hempel pipette, as well as a small quantity of the distilled water from the burette D (about 0.5 c. c.) the stopcock 3 is shut and the Hempel pipette is shaken for two minutes. This enables the permanganate to absorb everything but the amino nitrogen and the gas adherent in the acetate acid sodium nitrite solution. The water bulb is now lowered and stopcock 3 is permitted to communicate with the Hempel pipette, which causes a rapid return flow of water gas and permanganate solution into D. In permitting the return of the gas into D it is important to gather all the gas present in the bulb; this is accomplished by permitting a few tenths of a cubic centimetre of the permanganate solution to flow into the burette D and is to be deducted from the final reading. The stopcock 3 is turned neutral and the water bulb is raised on a level with the column of water in D and the quantity of gas read off. From this quantity is deducted the amount ascertained for the unabsorbable gas present in the nitrite solution, the remainder is representative of the amount present in 2.5 c. c. of serum. In order to express this amount in milligrammes of amino nitrogen the quantity obtained must be calculated first for one c. c. of serum and then multiplied by a factor which corrects the result for the variations of temperature and pressure according to the chemical laws governing the behavior of gases. This factor is obtainable from Gatterman’s tables, which were given in the first installment of this work. (Same title as this communication, New York Medical Journal, June 7, 1913.)

We consider an amino nitrogen content in the serum as normal when the amount obtained in 100 c. c. is 2.8 milligrammes or more. More than 2.3 milligrammes and less than 2.8 milligrammes is considered doubtful, and any amount less than 2.3 milligrammes is considered as significant of syphilis when the Wassermann reaction is also positive. The report of our present series of cases will be scheduled in six groups. The material comprising these various groups, with their respective diagnoses, treatments, spinal fluid findings, and remarks, will be given in the following tables:

The amino findings are as follows:

- Amino nitrogen diminished in 8 cases or 36 per cent.
- Amino nitrogen normal in 13 cases or 62 per cent.
- Amino nitrogen doubtful in 0 case or 0 per cent.

A résumé of the amino findings giving the results at a glance are embodied in the following tables:

#### GROUP 1.

- Lues clinically absent, untreated, Wassermann reaction — 117 cases.
- Amino nitrogen diminished in 20 cases or 17.1 per cent.
- Amino nitrogen normal in 94 cases or 80.9 per cent.
- Amino nitrogen doubtful in cases 5.9 per cent.

#### GROUP 2.

- Lues clinically absent, untreated, Wassermann reaction +, 12 cases.
- Amino nitrogen diminished in 3 cases or 25 per cent.
- Amino nitrogen normal in 9 cases or 75 per cent.

#### GROUP 3.

- Lues clinically present, untreated, Wassermann reaction +, 40 cases.
- Amino nitrogen diminished in 10 cases or 25 per cent.
- Amino nitrogen normal in 30 cases or 75 per cent.
- Amino nitrogen doubtful in 0 case or 0 per cent.

#### GROUP 4.

- Lues clinically present, untreated, Wassermann reaction —, 32 cases.
- Amino nitrogen diminished in 26 cases or 81.2 per cent.
- Amino nitrogen normal in 0 case or 0 per cent.
- Amino nitrogen doubtful in 0 case or 0 per cent.

#### GROUP 5.

- Lues clinically present, treated, Wassermann reaction +, 7 cases.
- Amino nitrogen diminished in 5 cases or 71.4 per cent.
- Amino nitrogen normal in 2 cases or 28.6 per cent.
- Amino nitrogen doubtful in 0 case or 0 per cent.

#### GROUP 6.

- Lues clinically present, treated, Wassermann reaction —, 21 cases.
- Amino nitrogen diminished in 3 cases or 14.3 per cent.
- Amino nitrogen normal in 18 cases or 85.7 per cent.
- Amino nitrogen doubtful in 0 case or 0 per cent.

The lesion that the above exposition teaches can be summarized in a few words, i. e., that a positive Wassermann reaction in a patient without lues can be checked by the estimation of the amino nitrogen in the serum. This is particularly evident in the series of cases in group 2. The number is luckily very small, nevertheless unpleasant consequences to the patient are very prone to happen if they are permitted to carry away the diagnosis based on a faulty or incorrect positive Wassermann reaction.

The question is in order as to the significance of the three cases in group 2, who also gave a diminished amino content. We believe that the safest procedure would be to use less serum (0.1 c.c.) and repeat the entire test, using freshly obtained blood. If the result is again positive, we are inclined to regard the positive result as expressive of syphilis, even though no clinical manifestations of its presence could be detected. In the laboratory of the Neurological Institute all questionable reactions are controlled by an amino determination.

### 30 BEEKMAN PLACE.

**THE AUROMETER.**

*An Instrument for the Exact Recording of Hearing and the Determination of Progress in the Treatment of Various Conditions of Deafness.*

**BY M. LUBMAN, M. D.,**

New York,

Chief Assistant in Ear, Nose, and Throat Department of Har Moriah Hospital.

The treatment for chronic nonsuppurative otitis media with deafness, tinnitus, etc., is to remove any mechanical or pathological obstruction that may interfere with the proper ventilation of the middle ear. Having accomplished this, we use local application to the Eustachian tubes, also vibration and inflation. The objects of vibration are: 1. To draw the sunken drum outward; 2. to break off adhesions of the valvular chain; and, 3. to improve the circulation of the parts. The objects of inflation are: 1. To clear the Eustachian tubes from blocked secretions; 2. to break off newly formed adhesions between the ossicles; 3. to push the drum outward; and, 4. to restore the normal tension between the drum head, ossicles, and the intralabyrinthine fluid. It would seem then that vibration and inflation could serve as specific for this disease; their use, however, is dependent upon the improvement, for if there is no improvement after the third visit, inflation should not be further attempted, as it is then absolutely contraindicated and injurious.

We are guided in the use of inflation in a given case by the tests that are at our command, which are supposed to register whether there is any improvement or not.

The tests are subjective—asking the patient if there is any improvement—and objective, the voice, whisper, watch, and the tuning fork.

Upon careful examination, however, these tests are unreliable, for we cannot depend too much...
very simple in its construction and is able to register improvement to a fraction of an inch.

The aurometer consists of a circular headband adjustable by a thumbscrew to fit any size of head (see Fig. 1). At the sides of this headband, opposite the ears, are extended two angular bars graduated in $\frac{1}{2}$ inches (see Fig. 2, B). On each bar is a sliding upright piece (c) controlled by a thumbscrew and with a small hook at the top to suspend a watch; the watch will be in the exact line of the external canal (see Fig. 3). As you will see in Fig. 1, the headband has two eye shields to obstruct patient’s vision, for obvious reasons. It is preferred that the watch should hang on a string from the hook, as it will prevent a solid contact of watch with the instrument to transmit vibrations.

It is by moving this sliding upright with the watch that gives us accurate data of the progress of the case.

78 East Fourth Street.

A TEST FOR ADULT IMBECILES AND SIX YEAR OLD NORMALS.

By Howard A. Knox, M.D.,
Ellis Island, N. Y.,
Assistant Surgeon, United States Public Health Service.

The average brain at each age during the developmental period of life is capable of a definite amount of mental effort and has the power to solve problems of a given complexity, just as each glass graduate from ten cubic centimetres to a litre is capable of holding a certain definite amount of fluid.

Now, knowing this, we say that a brain with insufficient ability to solve a problem (without previous training) of the proper complexity for its physical age is a defective one, and we classify the possessor according to the point in life where his mental development was arrested. Thus, if he develops not at all or but little, he falls into the idiot class; if he reaches one year of mental life and stops, he is a low grade imbecile; if he reaches six or thereabouts, he is said to be an imbecile, or, as some say, a high grade imbecile; if he stops at eight, he is said to be feebleminded; and if he does not pass the age of twelve mental years and he is in body four or more years older, he is said to be a moron or higher feebleminded.

Among educated persons the Binet-Simon test is an excellent means of classification, but in working with illiterates and their children, performance tests that demonstrate native ability and which presume no previous instruction, are better. The tests here-in described are meant to meet this indication. In fact all the tests in use at Ellis Island are adapted and standardized for use in working with those in whom no scientific effort at teaching has been previously attempted.

The author’s imbecile test, in addition to being of value in diagnostating adult imbeciles, is of value as a test for six year old normals, provided that in childhood they have not been in the habit of playing with similar contrivances. A normal child at the usual time of entering school (six years) should be
able to perform the test in less than one minute and thirty seconds with not over three "false moves" and one "mistake"; this was the average experience with twenty-five six year olds, who conformed to the Binet-Simon standards for that age.

The judgment of size and form should be a mental process entirely in the case of normal children using this test, and it should not be necessary to physically fit the pieces in the various spaces to determine their adaptability.

Sections 1, 2, 3, and 4 of the imbecile test are called books, and it will be seen that they are graduated in size, and the difference in size is just sufficient to be recognized at once by normal six year olds. When all the blocks are out of the frame, no obvious space is apparent for the circular section, 5, and to normals there are only two possible spaces where it can go, the centre and in the space for section 4. Attempting, therefore, to put 5 anywhere else would constitute a false move and should be recorded as such.

A mistake is the placing of a section in a space where it does not belong and removing the fingers from it. A false move is a case where the section is simply tried in the wrong space without releasing it from the fingers. The terms false move and mistake are thus defined to avoid confusion and to insure accuracy in reporting results. In our classification of imbeciles the number of false moves and mistakes are disregarded in this test, and those who in ten minutes cannot put the sections in their proper places are said to have qualified, in part at least, for the imbecile class, provided they have no physical disability that might interfere with the performance of the test, such as defective vision or paralysis.

This test is also used as an encouragement test at Ellis Island in working with suspected higher defectives, that is, it is given to them at the beginning of the performance test examination to inspire confidence, and to reassure them as to their ability to perform the more difficult performance tests suitable to their mental measure, of which the moron test shown here is an example. Experience with fifty subjects shows that illiterates and others who are ten years old or older should be able to put the four blocks in this moron test inside of three minutes and, furthermore, if the notched part of 2 be turned toward the space for 1 they should be able to correct this manoeuvre by turning 2 back toward 3 and completing the test by putting the other three pieces in place; in other words, they should understand the puzzle and not perform it by accident. To be sure of this the subject should be made to perform the test three times in succession and later in the examination also.

MYIASIS, OR FLY LARVAE AS PARASITES OF MAN.

With Report of a Case.*

BY MICHAEL G. WOHL, M. D.,
Philadelphia,

Demonstrator of Pathology and Curator of the Pathological Museum in the Medical Department of Temple University, Philadelphia.

That the infection of the human body by the larves of insects was known to the ancients seems certain by the mention that Homer makes of a man affected by a maggot. However, the first scientifically authentic cases seem to have been reported not earlier than in the sixteenth and seventeenth centuries. Thus, among the first, Leeuwenhoek (1687) speaks of a patient whose leg was infected by many small maggots, the species of which, however, were not ascertained. Hope, Chichester, Pickles, Sandberg, and Blanchard report cases of infection by beetle larvae. The presence of the fly larvea as parasites of man, first designated by Hope as myiasis, has been divided by subsequent investigators into myiasis interna or intestinalis, to describe the infection of the gastro-intestinal tract by the larvea; and into myiasis externa or dermatosa, to describe the occurrence of the larvea on the skin, in the nares nasi, frontal sinus, etc.

The term myiasis, hitherto loosely used in literature, has been more scientifically employed in conjunction with the name of the species to denote the proper classification of these larvea. Thus, myiasis intestinalis muscosa, or myiasis externa vastrosa. There is no doubt but that the field needs closer investigation, especially since the rapid advance of entomology enables us to properly designate the species. Among the dipterous insects, many families have been reported as having infected the human body with their larvea. We shall, however, turn our attention to the study of some members of the family sarcophaeae or flesh flies, and especially to the fly *Sarcophaga sarra-cinica Riley. Early records are kept about this fly; Plutarch writes that in Persia criminals sentenced to death were exposed to perish by these flies. Kirby and Spencer mention the case of a beggar who was accustomed to place his surplus contributions between his shirt and skin. On one such occasion, having thus hidden some meat and lain down to sleep, the meat was consumed by a fly, probably of a species of the sarcophaeae, and then his body was attacked. The man's breast was partly consumed, and death followed closely after transfereence to the hospital. (Kirby and Spencer, Introduction to Entomology, 1828; 1, p. 738.) The flesh flies are said to be uncommonly numerous in Paraguay. Azares recites instances in which patients, after having lied at the nose during their

*Read before the Pathological Society of Philadelphia, May 22, 1913.
sleep, were attacked by the most violent headaches, and did not feel any relief until large maggots—
the offspring of flesh flies—were extracted.

The larvae of these cases have also been frequently found in the ear. Dr. Walter B. Johnson, of Paterson, N. J., in an old number of the *Ophthalmological Record*, gives an account of the occurrence of maggots in the ear of one of his patients. The latter was an old, well-nourished man, who suffered from a long existing suppuring otitis media in the left ear, which had been under observation for some time. When admitted to Doctor Johnson’s infirmary an examination showed the external auditory canal to be filled with a mucopurulent discharge of considerable thickness, yellow in color, and excessively odoriferous. After removing this the tympanum was found to contain a large perforation, in which was noticed a white substance which was first thought to be exfoliated skin. Later the material was observed to move, and by using ear forcepts the object was seized and instantly removed. It adhered to the mucous membrane with a force sufficient to cause some hemorrhage. The larva was recognized as that of the flesh fly. It was full grown, and just at the point of transformation. (Abnormal Entozoa in the Human Ear—*Ophthalmological Record*, 1892, I, p. 274.)

How could we account for the particular situation of this larva? Doctor Lockwood suggests that it might have entered through the Eustachian tube when very young. Supposing the patient to have eaten cold tainted meat, and when a morsel was in his mouth to have coughed from some cause or other, or in some way to have dislodged a very young larva so that it was thrown onto, or near, the Eustachian tube orifice. The occurrence of larvae of the flesh fly in the human ear forms one of the most disagreeable complications of cases of otitis media purulenta. The insect is guided by the sense of smell to its food, to the depository of its eggs. Hence it is found generally in otitis media characterized by offensive discharges.

The larve of the sarcophaga were found in two cases under Doctor Blake’s observation. There was an extensive destruction of the membrana tympani and profuse otorrhea. Symptoms were shown in an increased deep seated pain with the sensation of some motion within the ear. The discharge became blood streaked. The larvae were seen as a whitish undulating mass filling the middle ear and the inner end of the meatus, and were extracted by means of forcepts. Five larvae were removed from each of the two cases. With the removal the pain and streaks of blood in the discharge ceased. (Archives for Ophthalmology and OtoLOGY, ii, 1872.) Mr. Ruthe (Wigm. Handbuch der Zoologie, 1832, p. 438) records the larve of the sarcophaga to have been discharged from an abscess in the ears of a man in Berlin on several occasions, though the image is rather rare there. Doctor Taschenberg, in *Gessam. Naturg.* xxvi. 1870, reported a case of Doctor Eylan, who extracted two larvae of the flesh fly from the ear of a boy of Merseburg, and he added that Mr. Brown wrote to him of similar cases that had occurred in Vienna.

Under favorable conditions the flesh fly may deposit its eggs in other places than in the ear.

Major James Kimball in the *New York Medical Journal* of 1893 reported the following case of myiasis of the nares:

**Case I.** Private J. J. S., 18th Infantry; complained of pain in the forehead and orbits, anorexia and fever. His temperature taken under the tongue was 102.4° F. He was admitted to the hospital and given the usual treatment for fever patients, but the following morning he was in a much worse condition. During the previous night, while he was sleeping at times, constantly tossing about and trying to get out of bed. He complained of intense throbbing pain at the root of the nose and over the frontal region. The nose and lower eyelids were red and swollen. There was a discharge of blood serum, from the left nostril, with an offensive odor. Chloroform was given by inhalation, and all the larvae that could be seen, about fifteen to twenty of them, were removed with a slender forceps, and then one dram of carbolized oil was injected into the nostril. The patient expressed great relief, but from time to time maggots were ejected in the act of sneezing or in the blowing of the nose. On September 21st the condition of the patient was worse than ever. Both eyes were painful at the sillling. Un.Osered, and most distressing. Maggots escaped not only from the nose, but from the mouth as well when in the act of coughing. The fetor of the breath was extremely offensive. The velum palatinum was swollen to such an extent that deglution was prevented. An injection was given of two drachms of chloroform (pure). The pain produced by the injection was allayed by injecting carbolized oil, and the nostrils were washed out by means of a postpharyngeal syringe with a ten volume solution of hydrogen dioxide. The eye and mouth were immediately and encouragingly relieved. Not less than a hundred dead larvae were expelled, partly by syringing, partly by sneezing, by forcibly blowing the nose, and by coughing out those which came down through the posterior nares into the pharynx. On September 23rd live maggots were again seen on looking into the left nostril, and the injection of chloroform was repeated for the third and last time. A score or more of dead larvae were gotten rid of on this occasion. In all less than three hundred maggots were ejected.

History. The patient said he had had catarrh since the last winter, and that for several months past the discharge had been offensive. The history he gave of the present illness was that on the afternoon of September 16th, about three hours before night, he had applied for medical aid while asleep on a bench in the barracks. He was awakened by a tickling sensation in the nose, which he thought was produced by a comrade with a straw. This, in all probability, was the time when the eggs or the larve were deposited by a fly within his nostril. The infection in this case proved to be caused by the sarcophaga.

The flesh fly is found very commonly around the butcher shops from about the first of March to the last of October.

Kimball, who reported this case, added that he obtained reliable information of seven cases of maggots in the nose (in addition to the one reported) occurring at Fort Clark and its vicinity, all of which except one proved fatal. Others existed in all patients. Attracted by the strong odor the fly enters the nostril when the victim is asleep to drop its living larve.

**Case II.** Patient was a soldier and had pain in both head and face. When bleeding from the nose commenced, maggots were discovered in the nasal septum. Treatment was unsuccessful and the man died. At the autopsy a great number of the maggots were found in the posterior nares and nasopharynx, some being free in these cavities and moving actively about, and others imbedded in the tissues.

**Case III.** Soldier, admitted to hospital with neuralgia of left side of face and epistaxis. Committed suicide. Sarcophaga (georgina) were found in the left nostril and left antrum.

Of the rest of the cases meager detail were gathered, and all but one proved fatal.
Herr Schnee reports a case of a patient, female: from an abscess of her nose he extracted numerous small maggots of the flesh fly, which occasioned much suffering. (Archiv für Naturgeschichte, 1853.)

Kuznetzov in Centralblatt für Bacteriologie, Parasitenkunde und Infektionskrankheiten, 1, xxx, p. 236, reports the following case:

Case IV. July 25, 1893, Kirgise D., aged thirty-one years, of strong constitution. On admission the mucous membranes were pale. Temperature was 38.3° C. The patient complained of vertigo, headache, insomnia and anorexia, and constipation. Chief complaint was frequent epistaxis. On examination of the nose nothing abnormal was found. The patient, however, continued to complain of itching and pain in the nose. A five per cent. solution of boracic acid was employed as a nose wash. The suffering of the patient was diminished. Later larvae of the genus sarcophaga escaped from the nostrils. The fever subsided and five days later the patient was dismissed.

This disease deserves special mention because it is of rather frequent occurrence in Siberia among the nomad tribes. Portshinsky-claims that infection by these larvae have been very frequent in Russia. Quoted by Gilberth (Archives for Internal Medicine, ii, 1908).

M. Legrande du Saule reports a case of a child nine years old, who had the sarcophaga in the frontal sinus. They were extracted through the nose. (Comptes rendus hebdomadaires des séances de l'Académie des Sciences, Paris, 1857, xlv, p. 600.)

The members of the sarcophaga have also been found in the eye. Professor Grube (Archiv für Naturgeschichte, 1853, xix, i, p. 282) records three cases:

Cases V and VI. Two boys, aged four and twelve years, had slept in the open field. On awakening, they felt some pain in the inner angle of the eye. There followed inflammation, destroying the eye, and the physician extracted twelve to fifteen larve nine lines long. Some of them were transformed into flies, which Professor Grube recognized as sarcophaga.

The following case shows that if the conditions are favorable the sarcophaga will deposit eggs in other situations than in those above mentioned:

Case VII. A soldier who suffered from remittent fever, was also the subject of constitutional syphilis, which was manifested at this time by ulcers of the gums with a very offensive odor. For several days he was in a semiconscious state. low delirium, and while in this condition a fly deposited its eggs in an ulcer above the upper incisors. The nurse discovered them and they were removed, forty to fifty in number, by brush and forceps. (Kimball, New York Medical Journal, 1893, Ixii, p. 273.)

Dr. H. A. Hagen received from Wright, Canada, a larva of the genus sarcophaga extracted from a swelling in the neck of a girl. In connection with this we might say that larvae of this family have been found in furunculous swellings beneath the skin, in the vagina, especially where there had been a discharge. Undoubtedly many cases reported as the finding of larvae of dipterous insects were really of the genus sarcophaga, but were either unrecognized or mistaken for another genus. Thus Hope reported and tabulated thirty-seven cases of myiasis by the muscae which were recognized as the Musca (Sarcophaga) carnea, Linn.

The following case came under the observation of the author:

A young man while on his vacation in a suburb of Philadelphia was suddenly seized with abdominal pain, followed by a profuse diarrhea. On examination of the stools about a dozen small larvae were found. At the suggestion of Dr. Joseph McFarland some of the larvae were bred on meat, and in the course of twelve days were transformed into flies, which were identified by Mr. E. T. Cresson, Jr., of the Academy of Natural Science of Philadelphia. The sarcophaga sarracini Riley. After treatment by saltpetre and calomel no more larvae were expelled. Since then there has been no further indication of the infection. The stages of transformation were as follows: Larva, September 22, 1910. Pupa, September 27, 1910. Fly, October 4, 1910.

The above collected cases from literature show that human myiasis externa sarcophagidae is not at all unusual. This case of myiasis interna sarcophagidae however, appears to be sufficiently unusual to warrant its being reported. The method by which the intestinal infection takes place may be explained by the following observations: It has been noted that this fly deposits its living young on tainted meat and on the carcasses of fish or near it. Herms, in his experimental study of sarcophaga in the Lake Laboratory, Ohio State University, also observed that the more moisture that is present in the fish, the greater is the number of young larvae deposited, and as soon as the liquids have been sucked from the accessible parts of the fish, the egg laying and depositing of young larvae ceases. Eggs and larvae are seldom, if ever, deposited upon fish that have become dry. (W. Herms—Experimental Study of Sarcophaga with Relation to Lake Breech Débris, 1907.)

The sarcophaga have also been observed by Howard (Proceedings of the Washington Academy of Sciences, 1900) to deposit eggs and larvae on exposed feces. Altogether ten cases where the larvae were captured on exposed feces were noticed by him. This species was also bred from excrement found in latrines at the camp of the district militia at Leesburg, Virginia, and it was also captured on feces at Marsh Hall, Maryland. This species seems to be common and widespread. (Howard, Proceedings of the Washington Academy of Sciences, 1900.)

Bouché found the larvae and eggs of the sarcophaga in rotten vegetables. (Proceedings of the Boston Society of Natural History, 1881.) This shows the necessity of covering all eatables, especially meat, fish, and vegetables, with something to protect them against the deposition of larvae and eggs. Although this fly has been found in houses, its presence there, however, is accidental.

The life cycle of the fly is as follows: The young larvae, when hatched, at once eat into the softer parts, attacking the viscera and later consuming the muscular portions. The fish is eaten clear as the skin and bone. On leaving the fish by migration the larva immediately burrow into the sand below or close by the fish. After the imago comes out it starts for the nearest grass to unfold its wings, and thus becomes an adult fly.

I desire to express my appreciation of the constant interest and advice of Dr. Joseph McFarland, under whom this work was completed, and to acknowledge further the kindness of Mr. E. T. Cresson, Jr., for identifying the fly.

Temple University.
EXPECTANT SCHOOL DISEASES.

By Harold B. Wood, M. D., D. P. H.,
Providence, R. I.

School efficiency is dependent upon attendance and attention at school. Both these factors are more dependent upon the individual health of the scholar than upon their scholastic abilities or willingness to work. Ability and desire are greatly influenced by the physical condition and vigor making aptitude. It is the defective who becomes the weakling; the defective who becomes slothful, careless, inattentive and backward. The physically defective is prone to become mentally defective, and mental defectiveness leads toward moral defectiveness.

Before a child is admitted to school he is examined for his scholastic fitness, and frequently thereafter he receives repeated examinations. A scholastic census is thereby taken of the school. The necessity of physical examinations to determine the conditions of the senses, brain, and body which are to undergo development has often been proven. Not alone is the taking of a health census a need, but the correct use of the information obtained is essential, that the little individual may be helped.

A school health census may be said to be comprised of two parts, a census or total enumeration of the physical defects of the scholars and a census of the various transmissible diseases. Each census is important and each should be obtained. Each varies year by year; the figures which represent the ratio of conditions tend to increase unless particular effort is taken to control them. Conditions of the home and the school influence the index of defects, but the widespread health control in the community largely affects the ratio of disease. From each census can be gleaned expectant results.

Poor school work is the expectant of a neglected defect census, poor attendance and broken classes result from lack of control of contagious diseases. So much work has already been done in discovering and correcting physical defects, that it is safe to state that in any school where medical examinations are not made and the existing defects corrected, there can be expected more or less of an increase of the defects, with backwardness, ignorance, disease, repetitions and waste of public funds.

A disease census of a school is the enumeration of the particular diseases which the school children have had during some specified time. The time herewith considered is all the time previous to the taking of the census. For the purposes of this article susceptibility is rather a historical than a physiological term. If a child has not had a particular disease he is herewith classed as being susceptible to it, an inference, however, which is not scientifically true. If a child has not had vaccinia or smallpox he is classed as being susceptible to variola. For the purposes of this article, and for school control of the infections, it seems safe to assume that when a child has had a disease he becomes immune from future attacks.

This would not be a safe assumption with diphtheria. It would be unsafe to consider that a case of diphtheria cannot become harmful when exposed to immune children. There would be more or less danger of those children becoming carriers. After a diphtheria case has been discovered in school and isolated, it is advisable to determine the presence of any carrier who may have infected the excluded child, or become infected by him. But with the other communicable children's diseases the occurrence of a second attack is so uncommon, or the danger of an immune child becoming a carrier is so little, that for the purposes of the same control of diseases in school the probability of such occurrences could safely be overlooked.

The disease census does not indicate absolute results, but simply indicates the approximate relative needs or attention due the scholars. Neither is there an absolute boundary line between conditions classified as physical defects and those accepted as normal or requiring no corrections. The census of past diseases is most reliably obtained from the parents, but this method has its objections. When the children are given blank cards to have filled out by the parents, the mothers are forgetful or do not understand the usefulness of the data or the children lose the cards. When the children are asked themselves in regard to their past history the answers are usually reliable, except with children in the first grade or with children of foreign extraction. Children and parents are apt to confound measles and German measles, and children are frequently sick of a contagious disease when a correct diagnosis is not made. These conditions vitiate the results of the census.

When diphtheria outbreaks in a school unless the carrier cases are discovered and eliminated a continuance of the outbreak can be expected, even though the patients be isolated and the room fumigated. Fumigation, at best, is of questionable service, and of little benefit if there still remain in the classes the children who are the carriers and distributors of infection. An indirect advantage of the school disinfection is that it compels the closure of the school for a while, during which time new cases have an opportunity to develop and become manifest, and hence are kept from school. After disinfection the room usually receives a good cleaning and airing, both of which are always needed.

A school census of diseases in a western town showed the following percentage of diseases which the school children had had at some time previous to the enumeration.

These figures include the classes from the first to the eighth grades inclusive, being a compilation of the diseases of 760 scholars in five schools.

A census taken of older scholars might show great variation from these figures. This percentage for scarlet fever is high owing to the presence of an annual epidemic of the disease for several years previous to 1913. The increase in mumps
was due to an outbreak of 354 known and uncontrolled cases among the school children. The percentage of immunity was raised from sixteen to sixty-one, if those children who had had mumps may be termed immune. An outbreak of measles in the same town, in which four tenths of the known cases were school children, influenced the census figures from seventy-one to seventy-nine. There were 150 cases among the school children. The increase in vaccination was the result of numerous talks by the health officer upon the subject. Compulsory vaccination is not legal in the state.

The disease census of one school may vary considerably from that of another. The great influencing factor is epidemics which may be local, varying in parts of the same city. A census of physical defects of different schools or of different localities is more or less uniform, for rural as well as urban schools. In many examinations of different schools throughout the Union, it has been shown that approximately twenty-five per cent. of the scholars have defective vision. But the percentage of children of an entire school who have had measles will vary considerably from the percentage obtained in another school or in another town. An outbreak in the school or a few cases will increase the disease ratio over that of the previous year. Conversely if there should be no outbreak of a certain disease among the scholars the disease ratio will decrease from year to year. This is due to the fact that the older scholars who had the particular disease have left school and the younger incoming school children have remained free of the infection, and hence lower the ratio of disease to susceptibility.

The proportion of susceptible children who will contract a disease upon a single exposure in a school room will vary considerably, being probably highest with measles and mumps. With the aforementioned measles outbreak the percentage of susceptible children who contracted the disease when the first-infectious child appeared in the room was sixty-five per cent., seventy-seven per cent., and eighty per cent. in three first or second grade rooms; sixty-two per cent. in a third grade and one hundred per cent. (three scholars) in a fourth grade room. The percentage of susceptible children is greater in the lower grades, but is more dependent upon school than upon town outbreaks.

For the purposes of estimating probabilities the school census is useful. If a case of communicable disease appears in a school room it is of value to be able to judge of the probable damage which is apt to accrue. Again, examples may be permitted. In two classes within the same building two cases of measles appeared about the same time. By the census it was learned that in one class of thirty pupils there were only three who had not had measles at some time previous. These three children promptly developed symptoms from the one exposure. To have closed the room would have been an injustice. None of the other children developed the disease. In the other room there were twenty-five susceptible children among thirty-five scholars. Of these twenty contracted measles from the same exposure.

When it is known that a school has suffered in the past from several contagious diseases the probabilities of future interference of school work from this cause will be lessened. The teachers and the school board then will be justified in outlining a greater amount of work, and have the assurance of little interruption and a hope of completing their expectations. If, however, the health officer or school physician knows that the susceptible are many, more vigor and watchfulness must be employed to prevent the outbreaks which would almost invariably follow the careless exposure of a few cases. If the susceptibility to a disease, as scarlet fever, were high in a certain class, greater precaution should be taken than if most of the children had already had the disease. If the class had suffered severely from scarlet fever in the past, when a new case appears there would be less need to close the school for a week or two and to isolate every child at home. With few or no susceptible children in the class a health officer might be justified in permitting the attendance of a child of the same family in which is a case of scarlet fever, measles, mumps, and whooping cough. It would hardly be safe to permit a child from an infected household to remain in intimate contact with a large number of susceptible children. The apparent duty of those responsible for the health of the school children is to determine the susceptibilities of those children and to control them according to their dangers.

The period of exclusion from school on account of transmissible diseases may be influenced or determined by the results of a school disease census. Unless definitely defined by law. With our present knowledge it is difficult to determine exactly when a case of scarlet fever ceases to be infectious. If a class from which a case comes is highly susceptible the class deserves the benefit of the doubt and the exclusion period should be long. It should probably be prolonged until near the end of desquamation, to give the throat ample time to clear. But if the census shows that nearly every child with whom the case would come in contact at school had had scarlet fever it would probably be much safer to return the child to school as soon as the throat had apparently become normal, and long before desquamation was complete. At this time the danger of transmission is slight, and it would be safer to have the child among his immune classmates than among the neighbors’ susceptible children.

A NEW APPARATUS FOR PROCTOCLYSIS.

By William D. Miningham, M. D.
Newark, N. J.

For a great many conditions it is desirable to introduce solutions into the rectum by the drop method. Each of the many devices for this purpose has its merits, but all are more or less faulty and very prone to get out of order. Most of them require the constant attention of some one to regulate the flow otherwise the solution will cease to flow or be expelled by the rectum. Nurses to whom this task is entrusted appreciate only too well the difficulties encountered in attempting to intro-
duce large quantities of fluids into the rectum. With most drop apparatus the water is cold when it reaches the rectum regardless of what the temperature may be in the container, unless hot water bags are used, which are objectionable for many reasons. A continuous flow of cold water into the rectum is not only undesirable but is less readily absorbed than when warm. From suggestions made by Dr. Edward J. III, I have had an apparatus which has given us entire satisfaction. By means of this apparatus it is possible to introduce from four to eight ounces of a warm solution at a uniform temperature every hour without giving the slightest discomfort or soiling of the bed, and with a minimum amount of trouble. The bottle need not be filled oftener than every five hours, depending upon the amount desired.

The apparatus\(^1\) consists of a vacuum bottle with a specially fitted brass stopper containing an outlet tube for the fluid and an inlet tube for air extending to the bottom of the bottle. The bottle is mounted on a stand with outstretched legs for steadiness. The writer is well aware that the vacuum bottle has been in use for this purpose for some time. The dropper, however, is original and has filled a long felt want. It consists of a glass barrel having an inlet tube with a stopcock attached and an outlet tube. The most important part of the dropper is the air vent which serves a double purpose. It not only eliminates any tendency towards a vacuum formation which would inhibit the flow, but also permits of the free expulsion of gases from the rectum without in any way contaminating the fluid in the container.

Next to venous infusion and hypodermoclysis, proctoclysis is the most valuable asset we possess in the treatment of shock and hemorrhage. It is a ready and efficient means of supplying fluids to the postoperative patient who is more or less nauseated and has usually been depleted of fluid by purgation. Inactive kidneys become active and toxicines well diluted. Thirst is satisfied and a feeling of well being predominates. Drainage cases will drain and so rid the system of poisons which would otherwise be retained. We have frequently given peptonized milk by means of the dropper and have on many occasions seen patients tided over critical periods by furnishing a continuous supply of a readily absorbable material.

448 High Street.

**Postoperative Treatment of Anal Fistula.**—Engel, in *Progrès médical* for April 26, 1913, reports good results from the use, after operation, of sitz baths in a solution of formaldehyde of varying strengths in water. Already on the day after the operation, while the patient’s bowels are being kept locked up with opium pills, two sitz baths are given, each of twenty minutes’ duration, with a two per cent. solution of formaldehyde. Later, the strength of the solution is gradually increased to eight per cent.; this percentage is generally attained on the tenth day after operation. At first the patient experiences a slight sensation of burning, but this soon disappears. The inflammatory process is rapidly brought under control as a result of the baths, and in most instances the operative wound is healed before the patient begins to go stool. The same is true when the baths are employed after operations for hemorrhoids. In the case of anal fistula, the patient removes in the bath the wick previously inserted along the morbid channel; a dry dressing is applied after the bath. After Whitehead’s operation the use of formaldehyde solution yielded most satisfactory results. The perianal cutaneous sutures were absorbed less rapidly after the baths than where these were not employed, and as a consequence the anal mucosa never became loose nor receded in the rectum. The postoperative treatment of fistula in ano was often markedly shortened through the use of these baths.

**Use of Opium in Incipient Gangrene.**—G. W. Gay, in the *Therapeutic Gazette* for July, 1913, points out that pain in the feet, and especially in the toes, of elderly people may be the initial symptom of an indolent ulceration which may terminate in gangrene. Most of the patients are victims of arteriosclerosis, and upon inspection of the limbs clear evidences of impaired local circulation will be

---

\(^1\)Made by Louis Stilling, Newark, N. J.
found, such as a dark, purplish color, slow return of blood after pressure, altered sensation and temperature, and lack of distinctness of the tibial vessels. To improve the blood flow in the extremities and increase nutrition, besides relieving discomfort, opium has appeared to the author to be far more effective than any other agent. The initial doses should be small. Ordinarily the author begins with two or three drips of the tincture, deodorized or simple, night and morning. This may be increased by one or two drops every four to six days until some improvement is evident either in relief of the pain or in the appearance of affected parts. The moment this is noted, the dose is to be maintained, or perhaps lessened a little. The author has never had occasion to exceed twenty drops in divided doses in the twenty-four hours. One of his cases has taken ten drops daily for about two years with benefit and no harm. The drug has seemed to act as a tonic, like strychnine, except that the improvement was much more apparent under the opiate than under the strychnine.

The drug should not be left in the control of the patient, nor need he know what he is taking. The physician or some reliable person should have charge of the "drops," to insure the proper dose and due restriction of the amount taken. With good management the drug can be used indefinitely with benefit. The stomach and bowels are not disturbed to any extent. Large doses would defeat the objects of the method, besides bringing about habituation. Cases are reported by the author illustrating the favorable effects obtained from the use of the drug.

Treatment of Pernicious Anemia.—J. A. Stealy, in the Lancet-Clinic for February 15, 1913, recommends Crofton's plan of administering hydrochloric acid to all cases of pernicious anemia showing diminished gastric acidity. The stomach being considered in these cases as an inert sac with scarcely any digestive or propulsive function, rich food is poured into it and artificial digestants—chemically pure HCl and pepsin—added. Ten to fifteen drops of the acid are given in mucilage water a few minutes after each meal, and the dose repeated in thirty minutes. For the preparation of the mucilage water, which is employed to prevent injury to the gastric mucosa by the acid, one ounce (thirty grammes) of pulverized acacia to one quart (1,000 c. c.) of water is used. One half glassful of the mucilage water is used to each dose of the acid.

It is important to carefully regulate the dose of the acid, for if too little is given the patient will not reap the benefit of the treatment, while if too much is given he will not retain the acid. In cases of complete achlorhydria, twenty drops of the strong acid may be given, generally in two thirds of a glassful of the mucilage water, while in some cases where the hypochlorhydria is slight but five drops may be needed. The dose should be changed in each individual case from time to time, less of the acid being required as the patient improves and the gastric production of hydrochloric acid increases. It is unnecessary to make periodic examinations of the gastric contents for the purpose of regulating the dose. One can tell from the patient's symptoms whether or not the dose is suitable. Excessive burning in the stomach or emesis after taking the dose is proof of the production of too great an acidity.

In addition to the acid treatment, the author administers sodium cacodylate daily by deep intramuscular injection, commencing with three quarter grain (0.05 gramme) doses, finally to reach a six grain (0.4 gramme) dose, and then gradually diminishing in frequency to every other day, every third day, etc. The diet is made a generous one, the various articles of food being prepared and served in the most appetizing way; psychotherapy is practised in the sense of giving verbal encouragement to the patient.

Treatment of Seascickness.—Auerbach, in Semaine médicale for June 25, 1913, is credited with the statement that to prevent or relieve seasickness a combination of caffeine, theobromine, and camphor is especially useful. The object of giving these remedies is, in particular, to overcome ischemia of the brain, which is believed to be an important factor in the production of seasickness. In adults, Auerbach prescribes 0.2 gramme (three grains) of camphor, together with 0.5 gramme (seven and a half grains) each of caffeine and sodium salicylate and of theobromine and sodium salicylate. It is necessary that these drugs be given in keratin coated capsules, in order that contact with the gastric mucosa, which would increase the nausea already present, may be avoided. Where a rapid effect is necessary, hypodermic injections of caffeine and sodium salicylate may be used. In particularly serious cases, moreover, intravenous injections of epinephrin might be of value.

Codliver Oil with Iron and Iodine.—C. Dietze, in Journal de Médecine de Paris for June 28, 1913, is quoted as recommending a mixture prepared as follows: In a small flask are placed:

- Ferri redacti, ............ 3i (4 grammes);
- Iodi, ............ gr. cxxiii (8.2 grammes);
- Etheris, ............ 5iiss (70 grammes).

The components are shaken up until the formation of iodide of iron is complete. There is then heated in an evaporating dish on a water bath:

- Olei morrhuae, ............ 5iiss (200 grammes).

Finally, after the burner has been turned out, the ether mixture is added to the oil and the product carefully stirred and then heated again to drive off the ether. After cooling, the mixture is filtered.

Treatment of Acute Myocardial Disease.—Sevestre, in Paris médical for July 5, 1913, is credited with the following combination, to be administered to children in whom the heart action becomes feeble or actual collapse supervenes in the course of infections such as diphtheria, typhoid fever, etc.:

- Caffeine, .......... ];
- Sodi benzoativ, .......... 3 gr. xxy (16 grammes);
- Spiritus sacchari, .......... 3iss (10 grammes);
- Syrupi toluinati, .......... 3iss (50 grammes);
- Aqua destillata, .......... 3ii (60 grammes).

NEW YORK, SATURDAY, NOVEMBER 22, 1913.

THE EARLY DIAGNOSIS OF INFANTILE SCORBUTUS.

Koplik urged, some time ago, the importance of an early diagnosis in infantile scorbatus. The importance of this statement is increasingly asserting itself. It is too often the lot of consultants to witness even advanced cases of the disease treated as instances of rheumatism, syphilis, epiphysitis, poliomyelitis, osteomyelitis, rachitis, purpura, infantile myxedema, and other disorders which include in their symptomatology one or more symptoms of scorbatus. De Sagher (Annales de Médecine et de Chirurgie Infantiles, VI, 1913, p. 165) recently referred to a number of patients in whom coxalgia, osteomyelitis and pseudoparalysis of syphilitic origin had been diagnosed, and in one instance, as to the last named disease, by a highly competent pediatrician. This emphasizes sufficiently the need of avoiding the oversight committed by the practitioner who, according to Northrup, admitted in consultation that he had "clean forgotten infantile scurvy."

As urged by Hutinell, infantile scorbatus should always be thought of first in every case of painful paraplegia in an infant, even when a child shows any degree of uneasiness when its legs are touched or when there is any tenderness on handling. These signs are usually first noticed when the babe is bathed. Even the paresis may not be noticeable, there being a voluntary tendency, in a child who has already learned to walk, to avoid doing so owing to the pain it causes. The latter is elicited especially when the pressure is exerted upon joints and bones, the tibiz for instance, the joints being perhaps slightly swollen. There is also a tendency to anorexia and anemia, the blood showing in some instances, marked hemoglobinemia, with corresponding reduction of the erythrocytes, and a failure to gain weight. Then may appear more typical signs of the disease: swelling or discoloration of the gums, ecchymoses, and hematuria. Either one of these phenomena may be the first to appear, however, along with the tenderness of the legs which is often taken for rheumatism or so called "growing pains." The swelling and purplish discoloration of the gums seldom appear unless there be teeth; when present as initial symptoms, they are often mistaken for difficult dentition and the gums lanced without, of course, the least benefit. On the whole, there is probably no disease which proves more misleading to the general practitioner; and it is probable that it is only regarded as a rare disease because it is very seldom recognized.

That infantile scorbatus is due to food deficient in materials needed by the child to carry on adequately the nutritional process is too familiar to require emphasis. Prominent as a cause, however, is exaggerated sterilization of the milk fed to the child. While sterilization at proper temperature cannot be definitely proved to deprive the milk of these properties (apart from its clinical effects) any degree of heat approximating the boiling point is known to be destructive to all the enzymes to which the milk owes its chemical properties. But this is not the only pathogenic factor; as stated by Crozier Griffith, the majority of infants with scurvy have been fed upon some proprietary food. This fact, the early symptoms mentioned, the age of the child—nearly always between the fifth month and the end of the second year—and finally, the wonderful curative effects of a change of diet and of fresh fruit juice, particularly that of the orange, are diagnostic features which should do much to prevent errors that entail a fatal issue in practically every instance.

THE TREATMENT OF PUERPERAL FEVER.

The frightful ravages of puerperal septicemia, until recent years, constitute an appalling and oft told history, and it is a well attested fact that the propriety of abolishing all lying in hospitals on account of the great mortality resulting from it in them was at one time repeatedly discussed. Even
as late as 1879, Playfair considered this a debatable question. The only excuse on the part of the medical profession for such a condition of affairs was the total lack of comprehension of the true causes of puerperal infection. Thanks to the labors of the great pioneers, Semmelweiss and Sir James Y. Simpson in Europe, and Oliver Wendell Holmes here, and to a host of others since their time, the marvelous change we now witness has been brought about; and, instead of the aggregation of parturient women being considered a risk almost too great to be undertaken, it is found that the mortality in the best lying in institutions is considerably less than in general obstetrical practice. The statistics of puerperal fever have been often rehearsed, but it may not be uninteresting to glance for a moment at a few figures from New York city records. In the eight years from 1868 to 1875, inclusive, there were reported in the city (comprising the present boroughs of Manhattan and the Bronx) 1,947 deaths from this cause—an annual average of 278.14, or a monthly average of about 23.18. As during most of this period the population was considerably less than 1,000,000, only reaching that number in 1875, and the population is now over 5,000,000, it is necessary to multiply these amounts by at least five to compare them with the present mortality. Now, for ten ten years preceding 1912, the average annual mortality from puerperal fever was 330, a decrease of 158 from the decennial average. In 1912 there were only 147 deaths, or a monthly average of 12.25. During the first six months of 1913 the deaths amounted to 147, a monthly average of 24.5. At present, however, there is a weekly average of but three deaths from this cause, and if this should continue to the end of the year, it would bring the monthly average down to 18.75.

While, therefore, the mortality from puerperal fever has been markedly reduced in the last few years, it still remains larger than it should be, and the fact that in this city there are more deaths from it this year than last emphasizes the need of still further improvement in the manner of both prevention and treatment. At the meeting of the American Medical Association in 1912, in consequence of the expression of two widely divergent opinions in the discussion of a paper by Dr. T. J. Watkins on the treatment of puerperal infection, a committee was appointed to make a collective investigation of the subject. This committee, consisting of Dr. B. C. Hirst of Philadelphia, Dr. R. L. Dickinson, of Brooklyn, and Dr. J. B. DeLee, of Chicago, made its report at the meeting this year, and it is now published in the journal of the association. From this we learn that the majority of accoucheurs and surgeons consulted, clean out the septic uterus at once, though a very considerable number hold that it is safe to trust the expulsion of its infected contents to nature; some assisting this by mild measures such as antiseptic douches and packing. The experience of the minority has shown that ovular remnants, even though infected, do not set up such dangerous conditions as was formerly supposed, and, moreover, there are many instances in which the infection is of such a nature, or the resistance of the patient so feeble, that the introduction into the system of the quantity of bacteria and toxines always resulting from curetting would prove fatal. This brings up the great desirability of distinguishing the benign from the pathogenic bacteria, but, as the committee says, we have as yet no method of making such a differentiation. Other points of interest brought out by the investigation were quite generally the tampon is used to stop hemorrhage in infected cases (there being apparently little fear of greater absorption from damming up the infection), and that almost invariably it was emphasized that when the uterus has once been emptied it should not again be invaded by either finger or curette, while few would permit antiseptic douches.

THE TYPHOID FLY.

When all the evidence shall have been garnered the domestic fly will appear as the greatest offender known to the sanitarian. Not only is this pest a mechanical carrier of infection, but, as shown by recent experiments performed by V. Ph. Berezoff at the Institute of Experimental Medicine in St. Petersburg (Rosssky Vratch, June 29, 1913), it harbors pathogenic bacteria in the interior of its body for long periods. This investigator obtained from the hospitals of St. Petersburg about 150 hibernating and frozen flies. After carefully disinfecting and washing the exterior, he dried the flies and made cultures from the contents of the intestinal tract. Powdered and emulsified flies were also injected into animals. By these methods, the author succeeded in isolating staphylococci, proteus and colon bacilli, streptococci, twenty-four varieties of nonpathogenic micrococci, a sarcina, twenty-five varieties of bacilli, two species of fungi, and some unidentified bacteria,—quite a formidable list. These bacteria, then, remained viable in the intestinal tract of the flies for four to five months. Another experiment performed by the author shows the menacing possibilities of the house fly still more forcibly. In the early spring, when the flies awake from their winter sleep, he fed a number of flies on cultures of pathogenic bacteria, the typhoid bacillus, the para-
typhoid, the pyocyanus, streptococci, diphtheria bacillus, and the cholera bacillus. In the course of a week the flies, having laid their eggs, died. The dead flies were then allowed to remain for a month or more and then treated in the same manner as the hibernating flies. In each case a pure culture of the organism on which the fly was fed was obtained, with the exception of the diphtheria bacillus, the paratyphoid A, and the cholera bacillus. These experiments prove that the fly may act as a splendid incubator for pathogenic bacteria, retaining them in a living state for months. It would seem that the usual method of swatting the fly is not free from danger, as the bacteria in the intestines may thus become liberated. Dead flies should either be washed down into a sewer or else cremated, the latter being probably the preferable method.

THE PSYCHOLOGY OF CROWDS.

In a section of his recent book, The Psychology of Revolution (Putnam's), Le Bon epitomizes the principles enunciated in his former work, The Crowd, A Study of the Popular Mind, and which he applies in the later work. Among these principles are: The man in the crowd is a very different being from the same man as an isolated individual; his conscious individuality vanishes in the unconscious personality of the crowd itself. Common passions and sentiments provoked by certain events are oftentimes sufficient to create the mentality of the crowd, which is entirely dominated by unconscious elements. Affirmation, contagion, repetition, prestige, constitute almost the only means of persuading crowds; reality and experience have no effect upon them. Their credulity is infinite; their sensibility is exaggerated; they are shortsighted, and incapable of responding to the influence of reason. The least excitement will lead them to act with the utmost fury. The man in the crowd becomes for the time being a savage, with all a savage’s faults and qualities (good and bad), with all his momentary violence, enthusiasm, and heroism; such a man becomes a child with all its irresponsibility. In the intellectual domain the crowd is always inferior to the isolated unit. In crowds gestures and physical actions are extremely contagious.

It would seem, however, that in all his notable books devoted to the exposition of psychology of crowds, Le Bon has dwelt very little, perhaps not at all, on the physical mechanism underlying the phenomena with which he has so brilliantly dealt; such mechanism is, however, easily understood in medical science. In the crowd the conscious has suffered inhibition, while the subconscious mentality has for the time being become supreme. The individual is in such deplorable circumstances precisely as one hypnotized; suggestion from without supplants the "kingship of all that is under one's hat" (to borrow Carlyle's noble expression); for the time being the nerve centres latest developed in human evolution—reason, judgment, selfpoise, intelligence—are shortcircuited; and the more primitive, fundamental, reflex ganglia, dominating the instincts and the emotions, are in control; the cerebrum has been debased, the spinal cord exalted. Le Bon has, as noted, well observed the contagious quality of gestures and actions in crowds. In the physical mechanism essential to such phenomena the action is suggestioned through the senses, a flow of blood, a congestion, is immediately determined to the motor area dominating the muscles concerned; and so all or at least many in a crowd at once duplicate the given act. Thus in the epidemic emotionalism characterizing some religious revivals those hideous movements, uncontrollable while strength remains by the Holy Rollers, the Holy Laughers, the Barkers, and the like are done in unison.

SAFEGUARDING THE SALE OF BICHLOORIDE TABLETS.

The Commissioner of Health of the City of New York has proposed for consideration two ordinances, one restricting the sale of mercuric chloride tablets to prescriptions, the other requiring that these tablets shall be sold only in the form of a triangle colored blue. This latter suggestion is the one put forth by the New York Medical Journal several months ago and we are pleased to see that it has commended itself to Commissioner Lederle. Several ill considered bills on the subject have been introduced in Congress. The National Drug Trades Conference, comprising representatives of all the national organizations interested in pharmacy, has been petitioned to take up this matter and will probably evolve some legislation which will safeguard the sale of this dangerous drug in a satisfactory manner. In the meantime manufacturers should refrain from offering it for sale in the uncolored discs which so closely resemble the remedies in tablet form which have such widespread popular use. An interesting note on the subject appears in this issue, in our department of Miscellany, which indicates that the present excitement on the subject is largely due to the sensational exploitation in the daily press of a comparatively small number of cases of poisoning.
Preliminary Note on Bedbugs and Leprosy.

David Thomson cites in the British Medical Journal for October 4, 1913, the reports made simultaneously by Long and by Sandes which state the finding of acid fast bacilli in a considerable number of the bugs fed on lepers, and he says that this leads to the presumption that these insects may play an important rôle in the spread of infection in this disease. Although Thomson has experimentally fed 105 bugs upon lepers, and has caught thirty-five from the beds of lepers, he has never been able to find a single lepro bacillus in any of the total of 140 bugs examined. Controls were run and were also free from acid fast bacilli.

News Items.

Changes of Address.—Dr. Edward Jackson and Dr. William H. Crisp, to 318 Majestic Building, Denver, Colorado.

The Harvey Society Lectures.—The fourth lecture in this series will be given at the New York Academy of Medicine, on Saturday evening, November 20th, by Professor G. H. Parker, of Harvard University, on the Nervous System, Its Origin and Evolution.

National Antinarcotic Meeting.—The American Society for the Study of Alcohol and Other Narcotics will hold its forty-third annual meeting in Philadelphia on December 3d and 4th. Dr. Alfred Gordon, 872 Spruce Street, is chairman of the local committee, and full particulars regarding the meeting may be obtained from him. Physicians and laymen are invited to be present.

The Montefiore Home.—The president and board of directors of the Montefiore Home have issued invitations to a reception to be held on the occasion of the dedication of the new buildings of the institution situated at Gunhill Road (East 210th Street) adjacent to Jerome Avenue, on Sunday, November 30th. The hours of the reception are in the morning from eleven to one o’clock, and in the afternoon from two to five.

The Washington Society of Nervous and Mental Diseases.—At the seventh annual meeting of this organization, held recently in Washington, D. C., the following were all reelected as follows: President, Dr. Tom A. Williams; vice-president, Dr. W. M. Barton; secretary, Dr. W. M. Hough. The society has a limited membership, but welcomes all physicians and surgeons who are interested in neurology and psychiatry. It meets monthly, on the third Tuesday, at the Cosmos Club.

Radiotherapy of Uterine Fibroids.—At a meeting of the Section in Obstetrics and Gynecology of the New York Academy of Medicine, to be held on Friday evening, November 28th, addresses on the subject of radiotherapy of uterine fibroids will be delivered by Professor Kronig and Professor Gauss, of the University of Freiburg, Germany. The subject will be discussed by Dr. George C. Johnston, of Pittsburgh, Dr. George E. Pfahler, of Philadelphia, Dr. Lewis Gregory Cole, of New York, and others.

County Medical Society Brings Suit against Proprietary Medicine Concern.—The Medical Society of the County of New York has brought suit against Edward J. Woods, Inc., of New York, on the ground that the concern is practising medicine without a license by marketing a medicinal preparation labeled with an explanation as to how the remedy should be taken by patients suffering from the disease it is supposed to cure. The case had been before the County Court, and has been adjourned to some future date. The County Medical Society has issued a warning to all other manufacturers of preparations similarly labeled that it intends to begin a wholesale prosecution of such interests, in the event that it is successful in its suit against the Woods concern.

Sea View Hospital Opened.—This new city institution for the treatment of tuberculosis, situated on Grymes Hill, Richmond Borough, was formally opened November 12th. It has been in course of construction during the last three years, and when entirely finished it will have cost the city about $3,500,000. There are eight buildings which furnish accommodations for one thousand patients. Dr. Edward S. McSweeney is superintendent of the new institution.

Ohio Valley Medical Association.—The following officers were elected at the annual meeting of this association held recently in Evansville, Ind.: President, Dr. A. D. Willmoth, of Louisville, Ky.; first vice-president, Dr. E. O. Smith, of Cincinnati; second vice-president, Dr. G. M. Young, of Evansville, Ind.; third vice-president, Dr. J. Riley East, of Indianapolis; secretary and treasurer, Dr. Benjamin L. Thompson, of Evansville, Ind. Next year’s meeting will be held in Evansville.

Meetings of Medical Societies to Be Held in Philadelphia during the Coming Week.—Monday, November 24th, Section in General Medicine of the College of Physicians, North Branch of the County Society, and the Germantown Branch of the County Society; Tuesday, November 25th, West Philadelphia Medical Association; Wednesday, November 26th, County Medical Society; Friday, November 28th, Neurological Society, Northern Medical Association, Section of the Academy, and the board of directors of the Medical Club.

Radium and Radioactivity.—At a meeting of the Section in General Medicine of the College of Physicians of Philadelphia, to be held on the evening of December 13th, the programme will be devoted to radium and radioactivity. The discussions will show the growing importance of radioactive substances in the treatment of disease, and both the scientific and practical sides of the subject will be considered. Among those who will participate in the discussion will be Dr. George H. Davison, of New York, and Dr. Howard A. Kelly, of Baltimore. A more complete programme will be issued later.

Personal.—Dr. Jay F. Schamberg has been appointed attending dermatologist to the Philadelphia General Hospital. He succeeded Dr. Charles P. Kayser. Dr. Aaron Aiken has been appointed professor of bacteriology and pathology in the University of West Virginia, and William Henry Schultz, Ph.D., has been appointed professor of pharmacology and materia medica in the same institution.

Sir Rickman John Godlee, president of the Royal College of Surgeons of England, had the honorary degree of doctor of laws conferred upon him by Toronto University, at a special convocation of the university on November 19th.

Clinical Congress of Surgeons of North America.—The following officers were elected on Thursday, November 13, 1913: President, Dr. John B. Murphy, of Chicago; vice-president, Dr. George E. Armstrong, of Montreal; secretary, Dr. Frank H. Marlin, of Chicago; treasurers, Dr. Allen B. Kanavel, of Chicago; business manager, Mr. A. D. Ballou, of Chicago. The next meeting of the Congress will be held in London, England, the fourth week in July, 1914. A special committee was appointed to take up the work of the standardization of surgery. This committee is composed of Dr. Lewis S. McMurtry, of Louisville, Ky., chairman; Dr. Charles A. Peck, of New York; Dr. Henry P. Newman, of San Diego, Calif.; Dr. William L. Cousins, of Portland, Me., and Dr. Charles A. Davison, of Chicago.

Anniversary Meeting of the Section in Laryngology and Rhinology of the Academy of Medicine.—The fortieth anniversary of the Section in Laryngology and Rhinology of the New York Academy of Medicine, which was originally the New York Laryngological Society, will be celebrated on Tuesday evening, November 25th, in Hosack Hall. The exercises will consist of an address by the founder, Dr. Clinton Wagner, an address of commemoration and the presentation of medals by Dr. Samuel Adolph, of Philadelphia, by Dr. Bryson Delavan, and the address of acceptance by Dr. William Wesley Carter. The committee, having the matter in charge is composed of the following members: Dr. B. Bryson Delavan, chairman; Dr. Thomas R. French, Dr. William K. Snowdon, Dr. William Wesley Carter, and Dr. Cornelius D. Van Wagenen.
Associated Physicians of Montclair, N. J.—This association held its first meeting for the season on Monday, October 23, and elected the members of the college, Henry Dwight Chapin, of New York, on a plea for a Broader Conception of Infant Feeding. A general discussion of the subject followed, among those participating being Dr. M. J. Synnot and Dr. J. F. Arsen, of Montclair. The next meeting of the association will be held on November 24th.

American Association of Clinical Research.—At the fifth annual meeting of this association, held in Chicago on November 7th and 8th, under the presidency of Dr. Franklin H. Rawson of the New York College of Physicians and Surgeons. The following officers were elected to serve for the ensuing year: President, Dr. Leonard K. Hirshberg, of Baltimore; first vice-president, Dr. Edgar B. Smith, of Detroit; second vice-president, Dr. George MacKenzie, of Philadelphia; registrar, Dr. J. D. Gibson, of Denver; secretary and treasurer, Dr. James Krauss, of Boston.

New Haven County Medical Association.—At the 129th semiannual meeting of this association, held in Waterbury recently under the presidency of Dr. Thomas M. Bull, of Naugatuck, the following officers were elected to serve for the ensuing year: President, Dr. Henry G. Anderson, of Waterbury; vice-president, Dr. P. W. Gailiard, of Branford; executive committee, Dr. Charles S. Rodman, of Waterbury, and Dr. Max Malhouse, of New Haven; chairman, Dr. William M. Baldwin, of Meriden; Dr. W. F. Verdi, of New Haven, and Dr. Thomas M. Bull, of Naugatuck.

The Hermann Knapp Memorial Eye Hospital.—This institution has opened its new building at the corner of Fifth Avenue and Twelfth Street, New York. It was founded in 1890 by the late Dr. Hermann Knapp under the name of the New York Ophthalmic and Aural Institute, and for forty-four years it has been in uninterrupted activity at 44 and 46 East Twelfth Street. On the completion of the old building in a new location, the board of trustees decided to change the name of the institution in honor of its founder. The new building is seven stories in height, fireproof throughout, and is equipped with all modern appliances for the treatment and study of the eye.

In Memory of the Late Doctor Fitz.—A memorial meeting to the late Dr. Reginald Heber Fitz was held in the Harvard Medical School on Monday evening, November 17th. Addresses were made by Dr. W. W. Keen, emergency chairman of the Medical Society of Philadelphia; Dr. Charles W. Eliot, ex-president of Harvard University; Dr. Henry P. Walcott, chairman of the Board of Health of the State of Massachusetts and chairman of the Medical Association of the State of Massachusetts; Dr. William S. Thayer, professor of clinical medicine, Johns Hopkins University, and Dr. William T. Councillman, Shattuck professor of pathological anatomy, Harvard Medical School.

First Convocation of the American College of Surgeons.—The convocation exercises of the American College of Surgeons were held in the Gold Room of the Auditorium Annex, Chicago, November 12, 1913. The names of the surgeons who were made members of the college were read by the secretary, Dr. Franklin H. Martin, of Chicago, and the president, Dr. J. M. T. Finney, of Baltimore, pronounced them Fellows of the college. The number of Fellows admitted was 1,050. Sir Rickman J. Godlee, president of the Royal College of Surgeons of England, was present. He was elected a Fellow of the college from the Council of the Royal College of England. In the message felicitations were conveyed to the Americans and hopes expressed that the college would grow and prosper and that by its influence the ideals and standards of every surgeon in America be advanced and maintained on a high plane. The following were made honorary members of the college: Dr. W. W. Keen, of Philadelphia; Dr. William S. Halsted, of Baltimore, and Dr. J. Collins Warren of Boston. A President Finney, in his address urged every member of the college to assist in raising the ideals of the profession and to erase the blots which now disfigure the escutcheon of the business of surgery. An important function of the college, he said, was to wage a relentless war against the evil practices with which the profession was tainted, chief among which was the pernicious practice of fee splitting and giving commissions.

Annual Meeting of Brooklyn Alumni.—The tenth annual banquet of the Alumni Association of the Cumber- land Street Street Hospital of Brooklyn, held on the evening of November 7th, Dr. William H. Pierson acting as toastmaster. At the business meeting which preceded the banquet, the following officers were elected: President, Dr. Nathaniel Robinson; first vice-president, Dr. geo. G. C. Godley; second vice-president, Dr. Henry P. Sage; secretary, Dr. Robert L. Wood; treasurer, Dr. George F. Lazarus, Dr. George H. Ilr, president of the Cumberland Street Hospital, was elected secretary for the ensuing year.

Southern Illinois Medical Association.—The thirty-eighth annual meeting of this association was held in Du Quoin, Ill., on Thursday and Friday, November 6th and 7th. There was a good attendance of physicians from St. Louis and other points in that part of Illinois, and this meeting was in every respect a great success. At the closing session Mount Vernon was chosen as the meeting place for 1914, and officers to serve for the ensuing year were elected as follows: Dr. W. L. Lilly, of East St. Louis, president; secretary, Dr. A. B. Cape, of Shawneetown; assistant secretary, Dr. H. E. Wilson, of Centralia; treasurer, Dr. J. W. Armstrong, of Centralia.

Treatment of Tuberculosis at Otisville Sanatorium.—The open annual meeting of the medical tuberculosis association, has received much less attention in this country than abroad and the favorable results obtained at the Sea Breeze Hospital, Coney Island, fully warrant the extension of this work by the city. Provision has been made to carry on for a certain number of cases in the Otisville Sanatorium, N. Y. Applications for admission should be made, as for adults, through the Associated Tuberculosis Clinics, which will, in turn, forward the application to the Hospital Admission Bureau, 426 First Avenue, Manhattan, New York.

Smallpox in Pennsylvania.—While it is reported that smallpox is prevalent in several localities throughout the State of Pennsylvania, the Department of Health is not alarmed over the situation as every case is being taken to prevent the disease from spreading. The records of the department show that there are sixteen cases in Carbon County, six in Altoona, four in South Lebanon, two in North Cromwell, one in North Lebanon, and one on the outskirts of Lebanon. It is said that a case of smallpox was discovered at Scranton, but it has not been officially reported. A few cases still remain in quarantine at Millhall, Clinton County, and several on the outskirts of Gettysburg, but no new cases have been reported from these localities for several weeks.

The Free Prescription Fraud.—In a number of publications advertisements are appearing which state that the person whose name is attached was saved from death through a serious disease by a prescription written by a physician of unusual skill who would not allow his name to be used because of medical ethics. The offer is then made to supply this prescription without charge. This prescription contains a number of ordinary ingredients and then, under a technical name, calls for a large proportion of some patent medicine or proprietary drug. The government cannot reach these people either the Food and Drugs Act or the Postal Laws, because the scheme is so planned as to evade government laws. The United States Department of Agriculture therefore warns the public against this fraud.

A New Course for Nurses at the University of Penn- sylvania.—A course in public health work for graduate nurses will be given at the University of Pennsylvania, by the University Medical School. The course, which will cover eight months, is divided into two terms, two months at the Phipps Institution Hospital and six months at the service department. The basis of instruction will be the treatment of and care of tuberculous patients, but every phase of sanitary work in the home, condition affecting the cleanliness of streets and dwellings, and the well being of the people in general. The general purpose is to give a course of lectures on the subject of medical inspection of school children and the segregation and care of mentally deficient pupils. Dr. Carl Kelsey and Dr. H. J. Neuringer of the University of Pennsylvania will deliver sociological lectures. Other lectures will be given covering every phase of the work, the staff of speakers including Dr. H. R. M. Landis, Dr. Paul A. Lewis, Dr. C. M. Montgomery, and Dr. Charles J. Hatfie.
The Pause in Audible Breathing.—R. Geigel noticed that in listening to the quiet breathing of a healthy individual there is at the end of expiration before inspiration a pause, during which the breathing continues, but is not heard. In feverish patients with increased respirations this pause disappears, and returns again stronger when the temperature declines and the respirations become less frequent and deeper. Therefore the presence of this pause, particularly in sleeping children, is not without diagnostic value.

Spirochetae in the Brain of Paralytics in Animal Experimentation.—H. Berger, encouraged by Noguchi's findings of spirochetae in the brain cortex of paralytics, vaccinated the testicles of rabbits with the brain substance obtained from a paralytic. In all two flies animals were vaccinated and observed for longer periods. In seventeen of the animals no syphilitic changes were demonstrable notwithstanding the minutest macroscopical and microscopical examinations. Only three cases showed in the substance of the testicle or epididymis slight local changes—whitish nodes and local focus of disintegration, the syphilitic nature of which could only be proved by the presence of the living spirochete. The vaccinated cases could not be distinguished clinically from the unvaccinated ones.

Complement Forming Reactions with Cerebrospinal Fluid in Carcinoma.—Dungern and Halpern out of twenty-eight tested cases of carcinoma found five which gave a positive complement reaction with cerebrospinal fluid, although no disease of the cerebrospinal nervous system was present. The cerebrospinal fluid reacted negatively in all other disease cases with the exception of lues. This proves that in carcinoma, even without clinical metastases, changes are present in the organism which point to a species of general infection.

Colloidal Palladiumhydroxydul Leptynol.—Gorn is able to corroborate Kaufmann's claims about the prompt and harmless influence upon aphoritis after the injection of leptynol. In none of the twenty-five cases thus treated was there the slightest complications or local reactions or aggravated general symptoms. The use of the correct technic for the injections is of utmost importance to success. It must be injected into the fat at least from two to three centimetres deep. The second condition for a successful cure is adherence to a strict dietary. The marked stimulation which the oxidation processes produce in the organism after the injection gives rise to the hope that the various psychoses, particularly akinetic obsessions in hebephrenics, may be, to a certain degree, favorably influenced.

Treatment of Malignant Tumors.—Lunckenbein makes a plea in this article for the use of subcutaneous injections of autolysat, i.e., tissue extract of the tumor in cases of malignant growth according to the suggestion of Von Rorsing. We commence with one cubic centimetre and when this initial dose is well borne, the dose is increased to from five to ten cubic centimetres. The autolysat can be kept fresh on ice for some time, although it gradually loses its effectiveness. This procedure gives the opportunity of active treatment, even in nonoperable cases of malignancy.

Salvarsan and Neosalvarsan Injections.—E. Schreiber answers the question, whether in place of the usual weak salvarsan and neosalvarsan solutions, a more concentrated solution with the corresponding lessened amount of fluid should be used in the following manner: When salvarsan is used a weak solution is best, since it is decidedly less toxic than the concentrated solution; when using neosalvarsan the concentrated solution is urgently recommended, since the danger of autooxidation is decreased in direct proportion to the lessened quantity of water used to make the solution. Physiological salt solution is the best vehicle, ten c. e. for 0.75 gramme of neosalvarsan. These injections are well borne, and are almost wholly without reactionary symptoms.

First Biological Radium Action.—Walkhoff emphasizes the fact that in 1900, that is one year before Becquerel discovered the biological action of radioactive substances, and not accidentally, as was later the case with Becquerel, but from purely experimental procedures.

Serology in Psychiatry.—A. Fauser reviews critically his own and the work of other investigators along these lines and illustrates with new serologic procedures particularly interesting psychiatric cases.

Metabolism in the Mentally Diseased.—A. Bornstein says in many cases of progressive paralysis, and still more in epileptics, an increase of the lecithin of the blood serum is found. That this increase in the lecithin in the mentally unbalanced is a sign of the breaking down of the brain substance is proved by Fauser's discovery, after Abderhalden's method, that in the insane the brain substance itself is attacked and decomposed. In dementia precox, in the vast majority of cases, a marked decrease of the initiative takes place. The author is inclined to correlate this with the disordered functioning of the sexual glands, and explains this decrease in dementia precox as a pathological intensification of a condition that accompanies normal puberty.

Acute Leucemia, with Genuine Transition Forms and Their Significance for the Independence of these Cells.—H. Reschad and V. Schilling report a case of acute leucemia characterized by an increase in the large mononuclears and transitory forms (so called splenocytes). Besides the myeloid and leucemic leucemias a new variety of leucemia is added, the splenocytic leucemia; and thus the splenocytes must be recognized as a distinctive cell.

Bacteriological Examination of the Urine in Acute and Chronic Nephritis.—A. Menzer answers Scheidemantel (Münchener medizinische Wochenschrift, No. 32) to the effect that ten years ago he insisted upon the etiological rôle of the excretion of bacteria in chronic nephritides, and
therefore urged a decided change in our present therapy of this disease.

Etiology of Infantile Paralysis.—J. Bruno's observations in the transmission of this disease by house pets make this etiological factor almost a certainty. Two small children, living in an isolated suburb of Heidelberg, were stricken with infantile paralysis without having come in contact with other persons. A few weeks previously a large number of imported ducks were stricken with peculiar paralytic symptoms and many of them died. It is to be noted that the whole family was sick for a few days—gastrointestinal symptoms, rheumatic pains and pains in the nape of the neck and small of the back. Bruno refers to other cases of a similar nature reported in the vicinity of Heidelberg.

September 16, 1913.

Arsenregenerin and Regenerin.—K. Dietl reports that regenerin (ovolecithin with 0.6 per cent. iron and 0.1 per cent. manganese, and arsenregene- rin (regenerin with 0.04 per cent. nitrate of arsenic and lithium cacodylate) are indicated in the treatment of cases where iron arsenic preparations are required. They are effective and have no untoward action.

September 23, 1913.

Experimental Arteriosclerosis and Cholesterinemia.—L. Nacker and W. Hueck find that by increasing the cholesterin content of the blood of rabbits for months it was possible to produce a diseased condition of the aorta which resembled in its main points an arteriosclerosis in the human aorta. From these experiments it may be concluded that in the pathogenesis of human arteriosclerosis hypercholesterinemia is etiologically important. This supposition harmonizes with the long established fact that all those factors which favor the appearance of an arteriosclerosis, as undue consumption of meat, muscular exertion, dyspnea, and certain poisons (narcotics) also increase the cholesterin content of the blood.

September 30, 1913.

Blood Serum of Gouty Patients.—K. Bass answers Ehrmann's and Wolf's article in No. 38 of this journal. In conjunction with Wiechowski he has proved that atophan has no effect in the first hours of its administration upon the uric acid in the blood, but later invariably causes a decrease. Also that the red blood cells are the chief source of the purins of the blood and the latter are not decreased in amount; further that uric acid is a constituent of normal blood. In its quantitative determination in the blood the use of certain definite methodical precautions are necessary.

Abderhalden's Dialysis in the Well and the Sick.—Third Report. Lampé and Fuchs report in this and in the previous issue that the serum of those suffering from Basedow's disease always disintegrates the thyroid glands in Basedow's disease and also to a less extent the thyroid of normal individuals. At the same time a reduction is observed, in most of the cases, of the thymin and generative glands. In myxedema disintegration of the thyroid gland tissue is also frequently present. In endemic goitre Abderhalden's reaction is positive for the thyroid gland.

ZENTRALBLATT FÜR CHIRURGIE.

Resection of Carcinoma of the Esophagus in the Cardiac Segment.—Eugen Bircher made a transverse incision and then one perpendicular to it along the ends of the ribs on the left side, broke in the ends of the ribs and thus obtained a large field for operation. The cardia was dissected free, its nutritive vessels ligated, the hiatus esophagus opened by blunt dissection, the tumor, which reached about one centimetre into the mediastinum freed in the same manner and brought down. The esophagus was tied off, the stomach seized with forceps on the ventral side of the tumor, and the tumor removed. As it seemed hopeless to try to unite the esophagus and stomach again, the end of the esophagus was invaginated, and a gastric fistula formed. Unfortunately the patient died a few days later from pneumonia.

PARIS MÉDICAL.

Colpotomy in the Treatment of Grave Puerperal Infection.—F. Jacoulet asserts that incision through the vaginal vault is indicated whenever, in conjunction with severe general symptoms of infection, the uterus is found large and tender, the vaginal cul de sac bulging downward, painful and fluctuating, and fetid fluids, with placental remnants, are observed issuing through the half open cervix. It is also indicated where, the examination showing nothing but uterine involvement, curettage fails to relieve the general infectious symptoms in twenty-four to forty-eight hours. In cases seen some time after delivery or abortion, i. e., where the condition is not septicemic but represents a pelvic localization of the infection, a hard tense mass being found in the cul de sac of Douglas, or where there is suppuration between the layers of the broad ligament, colpotomy is likewise to be recommended. In case of doubt as to whether there is exudate in the peritoneal cavity, the operation should be performed nevertheless. In many instances anaesthesia is unnecessary. Careful curettage of the uterine cavity should precede. The vaginal incision should be made transversely, a few millimetres below the line of union with the cervix, and should be about four centimetres long. If, as is sometimes the case, the pus then fails to appear, the finger should be used to explore behind the uterus, the tube being opened, if indicated, with a curved clamp slipped along the finger. A long cross shaped drain should be inserted behind the uterus to its fundus. The aftertreatment should be that appropriate for peritonitis. Even when but little fluid is evacuated by the incision, much benefit may ensue, and with the field for colpotomy extended in accordance with the indications already stated, unexpected recoveries from severe puerperal infection will often be obtained.

Treatment of the Anemia of Rheumatic Patients.—H. Dausset states that in the anemia, sensitiveness to cold, and local tenderness often remaining for some weeks after an attack of acute articular rheumatism, as well as present in chronic rheumatism, diminished heat production in the body...
and impaired vasomotor regulation are important accompanying or causative conditions. He recommends applications of hot air to one half the body, electric light baths, baths in hot water gradually cooled, or diathermy, to make up for caloric deficiencies, reeducate vasomotor control, and also to promote elimination of toxins by virtue of the sweating induced. The first named measure is carried out with the lower limbs in the hot air apparatus. After air at a temperature of about 100° C, has been applied for fifteen or twenty minutes, slight discomfort may be experienced, the pulse rate rising to 80 or 100 and general perspiration appearing. The apparatus is now removed, and cologne water applied over the entire body with a cold, wet cloth, thus diminishing radiation of heat and arresting perspiration. If the procedure is interrupted when only slight sweating has taken place, no secondary depressing effect will follow. Electric light baths should be given, not in a closed cabinet, but with the patient and bulbs enclosed merely in an ordinary sheet. Both the general and local conditions are greatly benefited by a series of such baths administered daily or on alternate days.

**Distribution of Arsenic in the Viscera after Salvarsan Injections.**—Jeanelmé, Vernes, R. Bertrand, and M. Bloch estimated the amount of arsenic in various organs of three patients who died of intercurrent causes at varying intervals after salvarsan treatment. In two, treated respectively, a week and nine months before death, the spleen contained the largest proportion of salvarsan, but the order of arsenic content in the other organs differed considerably in the two cases. In a third patient, dying of interstitial nephritis about eleven weeks after a badly borne intramuscular salvarsan injection, the largest portion was found in the kidneys; in this case the customary discharge of arsenic in the urine several days after the injection had not taken place. In a fourth patient, probably with amyloid degeneration of the kidneys, who developed anuria after an intravenous injection of 0.1 gramme of salvarsan, one sixth of the arsenic introduced was found in the blood stream during the period of anuria, showing that, when renal elimination is blocked, the drug remains in the circulation some time before being deposited in the tissues. After comparing their results with those of previous investigators, the authors conclude that in different cases the arsenic may become fixed by preference in the spleen, liver, nervous system, or lungs, without there being any apparent reason for such selective localization. Where the function of the kidneys fails, however, the arsenic seems to accumulate there.

**REVUE MÉDICALE DE LA SUISSE ROMANDE.**

September, 1913.

**Paraoxyphenylethylamine.**—A. Mayor and B. Wiki have found this substance, one of the active principles of ergot, of relatively low toxicity in animals: 0.25 to 0.3 grammes intravenously per kilogramme of body weight being required to produce death in rabbits. In small doses it stimulates the heart and constricts the vessels, causing a rise in blood pressure. The vasoconstriction is the result of stimulation of the end organs of the vasomotor system in the vascular walls. This substance is a powerful excitant of the uterus. In large amounts it causes convulsions—due, unless the dose is such as to cause prompt death, to direct stimulation of the central nervous system—and also direct depression of the heart muscle. Though it is chemically related to epinephrin, and can be considered as a species of mitigated ephrin—fifty to one hundred times more being required in the rabbit to cause a rise of blood pressure than in the case of the latter substance,—it possesses certain special properties of its own, viz., the direct cardiac depression already mentioned, causing a primary fall of blood pressure after large doses and killing the animal without concomitant pulmonary edema; also, the production of bradycardia in the absence of any marked or lasting action on the vagus centres, little or no acceleration taking place, during a period of cardiac slowing, when the vagi are cut, and stimulation of the peripheral cut end of a vagus at this time almost always causing a lasting acceleration of the heart beats instead of inhibition.

**Hereditary Transmission of Sarcoma.**—J. S. Manson reports the histories of three patients—a mother and two of her three sons. The mother had always been a healthy woman, but at the beginning of 1896, a lump about the size of a bean appeared on the left side of her neck. This grew slowly, reaching the size of a walnut in about eighteen months. At this time the youngest son was born, and after his birth the tumor grew very rapidly, causing her death from exhaustion in February, 1898, about two years from its first appearance. This was diagnosed as a lymphosarcoma, but no sections were taken. The youngest son remained healthy until 1912, when he was fifteen years old. At this time
he noticed a lump about the size of a walnut on the left side of his neck. A piece of this was removed and proved to be round, solid, and yellow. About a year and three months later he died of exhaustion, the tumor having grown very large and ulcerated. In his next older brother an inflammatory enlargement of his right tonsil and the lymphatic glands developed on the same side of his neck in 1912, at the age of eighteen. These glands were removed and found to be enlarged through chronic inflammation only. In 1913 he had bleeding from the right tonsil, which was enlarged, and at this time a tumor of small size was observed on the left side of the neck over the middle of the sternomastoid muscle. This was removed and found to be lymphosarcoma; a portion of the right tonsil removed at the same time showed inflammatory enlargement only. Local recurrence took place, involving the left tonsil and adjacent structures in the neck and floor of the mouth. Death took place in August, 1913, from exhaustion. Tracing the family history of the mother back as far as possible, no history of malignant disease was found, except in two paternal grand aunts. Manson believes that the sarcoma did not arise de novo in the mother of the two boys, but was the result of a hereditary variation or sport. If the sarcomas in the two boys are regarded as being of hereditary origin—and for this view there seems much evidence, both in the nature of the growths and in their location—the law of anticipation is well illustrated; the boys died at the ages of fifteen and nineteen, respectively, whereas their mother died at the age of twenty-nine years. If the hereditary character of these two cases in the boys be granted, then the observation lends some support to the theory of embryonic cell rests, as offered by Cohnheim and others.

Treatment of Scars by Multiple Incisions and Thiosinamin.—A. H. Tubby uses a fine and strong backed tenotomy knife and makes a large number of incisions in the scar tissue, transversely to the long axis of the scar. The incisions should not be more than a tenth of an inch apart, and they should extend both into the subcutaneous fat and for about a half an inch into the adjacent healthy skin. Pressure alone is used to stop the hemorrhage, and when this has ceased, a solution of thiosinamin is thoroughly rubbed in. If the scar tissue is very thick, a few drops may be injected into the most prominent bands. As much as fifteen to twenty minims may be injected at a time in an adult. After operation and injection the part is splinted in a position of extension to the greatest possible limit without tearing the soft tissues. After healing, which takes place with little reaction and very slight pain, it may be necessary to repeat the operation and fixation one or more times. The results with large contracted scars have been so good in the hands of Manson that he advocates a thorough trial of the method by others.

Supercorenal Sutures.—Ernest E. Maddox's experience contradicts the general idea that sutures should not be allowed to pass across the cornea. He finds that there is no ill result from their presence if they are previously waxed to render them smooth and nonadhesive. As a result of this observation he has devised a new operation for the treatment of conical cornea. It consists in excising a bilobate piece from the cone, after which a flap of conjunctiva, previously prepared and threaded, is drawn over the cornea in such a way that its tension will be at right angles to the long axis of the gap. This flap draws the edges of the gap together and at the same time closes the opening into the anterior chamber. The uniform pressure of this flap upon the whole cornea during the healing process tends to restore its roundness. The flap does not tend to adhere to the underlying cornea.

Persistence of the Nerve Plexus of the Iris.—W. B. Inglis Pollock dereserved the iris in albino rabbits by excision of the ciliary and superior cervical ganglia. After an interval of two weeks from the operation, in each case, histological examination showed that there remained a motor plexus with nerve cells, in both the sphincter and dilator pupillae muscles. This plexus was found to persist even after the complete separation of the iris from the central nervous system by the removal of the ganglia.

The Nature and Degree of Specific Differences among Bacteria.—F. W. Andrews directs attention to the fact that the criteria by which the naturalist determines species—morphological characters, capacity or incapacity for inbreeding, descent from a common known ancestor, and geographical distribution—cannot be applied to the separation of bacteria into species. Among the bacteria sexual reproduction and conjugation are unknown. This lack of sexual reproduction tends to the production of extreme variability among the bacteria, for there is no means of effacing chance variations. The doctrine of the noninheritance of acquired characters may not apply to the bacteria, for they present continuity of both germ plasm and somatic plasm. The influences of environment upon bacteria can become apparent in a very short time, on account of the extreme rapidity with which these organisms multiply. These considerations explain the existence of a very high degree of variability among bacteria, especially in relation to their pathogenic properties. Andrews suggests that the increase in virulence of a given strain of organisms which is brought about by animal passage is to be explained upon the basis of the "survival of the fittest," that is, only those among the organisms introduced which retain pathogenicity survive, and it is from these that the new strain arises. Many other physiological characteristics can similarly be developed, such as various powers of fermentation, etc. Therefore, he says, "It follows that it is only with extreme caution that such characteristics as pathogenicity or metabolic capacity can be regarded of specific value. Of the criteria employed by the ordinary naturalist in discriminating between species only one can be used by the bacteriologist—namely, the morphological one." It is possible, readily to arrive at a classification into certain wide families of bacteria, such as, the cocci, spirilli, bacilli, etc., among which we encounter Gram positive, acid fast, and other distinct genera. "If the foregoing facts are true—and I do not think they will be disputed—we are
entitled to conclude that, although bacteria are more
variable than the majority of living creatures, they
are by no means indefinitely variable. The vari-
a tions are seen within the generic group limits, but
do not transgress these." While there are definite
species to be found among certain genera of bac-
teria, Andrews believes that, among the bacteria
which are pathogenic for man, rigid specific limits are
often wanting. From a close study of the strep-
tococci from a statistical basis Andrews concludes:
"They are a labile group from which types are
emerging, which can be recognized by suitable
methods, but which are at the present day for the
most part undeserving of specific rank." Much the
same may be said of the coli group. Regarding the
chemical properties of bacteria, Andrews feels that
these are, like the morphological properties, subject
to evolutionary laws, and that it is, "a question of
adaptation of the organism to its environment and
survival of the chemically fittest."

Two Years' Experience with Salvarsan.—
Malcolm Morris and Henry MacCormac base their
remarks upon the results of 350 injections of sal-
varsan and 150 of neosalvarsan. They believe that
the newer drug is inferior to the older one, being
decidedly less active even in equivalent amounts,
and being very liable to undergo decomposition in
solution, with the production of highly toxic bodies.
All of the author's injections were given intraven-
ously, and by the use of freshly distilled, autoclaved
water they have almost completely eliminated fever
as a sequel to the administrations. They always
use full doses unless there is some definite contrain-
dication. Their results lead them to believe that the
remedy is of the utmost value in bringing about a
very prompt disappearance of symptoms, particu-
larly in the first and second stages of syphilis, and
they state that, the earlier in the disease the remedy
is given the more pronounced and rapid will be the
benefit derived. They do not hesitate to give re-
peated doses, but they do not advocate their use as
a general practice. They believe that salvarsan can
hardly be considered as a cure for the disease, and
emphasize the necessity for the continued use of
mercury for at least two years after the adminis-
tration of salvarsan.

Pituitary Tumor and Sellar Decompression.—
Wilfred Harris and Cecil Graham report a case of
such tumor in which this operation gave prompt
but temporary relief. They call attention to the
fact that most pituitary tumors reach such a size,
before they cause definite symptoms, that it is im-
possible to remove them through the floor of the
sella. They, therefore, advocate decompression,
which they perform as follows: An incision is made
in the exact middle line of the nose and is carried
clear back to the nasopharynx in this line, separat-
ing the two layers of the nasal septal mucosa but
not entering the nasal cavity. The middle turbinals
are forced apart by pressure with a metal glove
stretcher and the sphenoidal ostia are thus exposed.
The mucosa covering the anterior wall of the
sphenoid is gently elevated to give a perfect view
of the ostia. The floor of the sphenoidal fossa lies
about ten centimetres from the junction of the nasal
vestibule with the upper lip. A probe, marked at
a point ten centimetres from its tip, if placed against
the floor of the vestibule of the nose at the junction
with the upper lip, and directed in a plane which
corresponds with a line running from the nasolabial
junction backward and upward to form a tangent
with the lower and outer margin of the orbital cavi-
ity, will, when introduced for ten centimetres, im-
pinge upon the floor of the pituitary fossa. The
floor of this fossa is then removed by chisel and
burr, and the decompression can readily be com-
pleted.

Hereditary Chorea, with Report of a Case.—
William A. Boyd reports a case of Huntington's
hereditary chorea, which developed in a patient
twenty-six years old, an age that is much younger
than usual, and in whom no suicidal tendencies have
as yet been observed. The patient has been under
sanitarium treatment for about a year. A chart
showing four generations of the family demon-
strates the hereditary character of the disease.

Verruga Peruana, Oroya Fever, and Uta; Preliminary Report of the First Expedition to
South America from the Department of Tropical
Medicine of Harvard University, Headed by
Prof. R. P. Strong.—From the remotest histori-
cal times the inhabitants of Peru are said to have
suffered severely from the obscure disease, verruga
peruana and Oroya fever. From its investiga-
tions the commission concludes that these represent
two distinct diseases. The former is due to a virus
which may be transmitted to animals, producing
definite lesions in them, while the latter is due to a
parasitic organism in the red blood corpuscles suf-
ciently distinct from the other hematozoa to be
placed in a new genus. This parasite, which so far
has not been successfully transmitted to the lower
animals, produces in man fever and, in severe in-
fec tions, a rapid and very pernicious form of
anemia, frequently resulting fatally. From the
present evidence it would appear that the organism
observed in the blood in Oroya fever belongs to a
group of microorganisms intermediate between the
protozoa and the bacteria. Verruga peruana is a
disease particularly characterized by an eruption
on the skin and occasionally the mucous membranes,
especially of the mouth and throat, which presents
great variations in appearance. The distribution of
the cutaneous eruption somewhat resembles that
seen in yaws, but in many other respects the lesions
of the disease are entirely distinct. In uncom-
pl icated cases the parasites of neither Oroya fever
nor malaria are present in the blood. It is quite evident that verruga peruana represents an entirely distinct disease; and that it is not a form of frambesia or of syphilis. The investigation showed that uta, another ancient disease in Peru, is due to a species of Leishmania. The flagellate stage of the organism was obtained, and animals were successfully inoculated from a human case. In both Suroco and Otato (the latter town deriving its name from the prevalence of the disease there) a large proportion of the inhabitants are either afflicted with uta or show the disfiguring scars on the face, arms, or legs which have resulted from a previous attack.

**Untoward Results of Nephrolithotomy.—**M. Krotozyner, calls attention to the mortality following this procedure and such results as hemorrhage, perineal infection, septic nephritis, and fistula, and then compares pyelotomy and primary nephrectomy with nephrolithotomy. He concludes (1) that nephrolithotomy is connected with serious immediate and remote untoward results; (2) that it should be, whenever feasible, replaced by posterior pyelotomy; (3) that nephrectomy is the simplest, quickest, and safest curative method for pyonephrotic stone kidney, provided the function of the other organ is satisfactory.

**Decidual Reaction in the Appendix in Intrauterine Pregnancy.—**G. W. Outerbridge states that, so far as he has been able to ascertain, the occurrence of this reaction in the appendix has been observed in but one instance, reported by Hirschberg in 1905. Although in this case the appendix was closely adherent to the gestation sac, Hirschberg ventured the opinion that the presence of such adhesions is not to be considered a sine qua non for the occurrence in the former of decidual reaction. That he was right in this assumption and that, moreover, decidual reaction can occur in the nonadherent appendix in connection with normal, intrauterine pregnancy, is shown by a case which the author reports in detail. In this instance, he says, the intense appendicular inflammation present undoubtedly furnished the irritative stimulus necessary to produce the reaction. That a similar reaction is not found in all inflamed appendices removed during normal or ectopic pregnancy is probably to be explained in the same way as its failure to occur, in some instances, in the tubal mucosa or in any other of the numerous extrauterine situations in which, in other instances, it does develop.

In a note he states that after he had corrected the proof of his article a second instance of distinct decidual reaction in the appendix in conjunction with normal pregnancy came to his notice.

**MEDICAL RECORD.**

**November 8, 1913.**

**Neurovascular Gangrene.—**M. D. Bloomfield is convinced that what so often is considered a distinct disease is in reality only a "stage," a manifestation of the phenomenon first thoroughly elaborated by Raynaud, who reported it in 1862 under the heading, "local asphyxia and symmetrical gangrene of the extremities." On this continent the disease is most frequent among Hebrews. Males are more commonly affected, and most patients pursued an occupation necessitating long hours of standing or work requiring pressure on the feet, or were exposed to the severities of all weather—conditions interfering with the venous circulation. It seems probable also that microbic injection may be concerned in the etiology. The disease may manifest itself in three forms, regional ischemia, regional cyanosis, and regional hyperemia. Whether the gangrene is preceded by a neuritis or whether the lumen of the veins and arteries becomes occluded by thrombi is difficult to determine. The disease may shorten life, but in itself is not fatal. The author believes that this is a surgical malady, though the patient should, of course, be given a fair opportunity to receive conservative medical treatment. Personally, he has tried almost every known remedy, but has found none to which he could ascribe any curative powers. He holds that if amputation were done early, suffering would diminish appreciably, exhaustion be prevented, and a greater degree of safety to the life of the patient and a better chance of recovery he offered. Lines of demarcation should never be waited for; when they come it is too late to amputate. Mental diversion and heat, with plenty of nourishment, are the best means thus far at our command from a medical standpoint.

**The Neuroses and Psychoneuroses of Children: Their Mode of Development and Treatment.—**In these affections, B. Rosenbluth says, the pathologist can find nothing but immaturity of the child's brain. The most frequent manifestation of juvenile mental disturbance is a motor expression of a spasmodic character, and a large number of the motor neuroses of children are those of facial grimaces. The management of these cases is very trying. They demonstrate a disturbance, the manifestations of which are due to faulty environment. This environment being created by the family and friends, these have to be trained, so that the environment may be changed. Having referred to a neurosis consisting of a bilateral tic of the eyes, he states that of the more complex psychoneuroses, the one most frequently met with is a motor expression of mental disturbance which is characterized by general spasmodic movements of the entire body. Nocturnal enuresis and night terrors are also treated of. The most fixed and common neurosis of childhood is that of defective speech, represented by stammering and stuttering. In concluding, he says that in the child, whose sphere of action is limited, it is easy to lay bare the psychological content of any given experiences, and, by the early training of minds which have not been trained to adjust themselves to their proper environment, we can prevent more grave maladjustment in later life.

**Is Sterilization Destined to Be a Social Menace?—**In this paper G. F. Lydston, a pioneer in the matter of sterilization of the socially unfit and still believing it of great value, discusses some of its possible evils. In speaking of sterilization as a possible menace to the State he says that the assumption of the responsibility of procreating and rearing children demands a certain degree of self abnegation which many of both sexes gladly avoid. Not only will sterilization appeal to the male sex, but also to the female, perhaps in some instances more strongly, because the burden falls
most heavily on the female. The Economic Phase of Sterilization.—The increased cost of living bears particularly on the expense of rearing a family, and as economic conditions are likely to grow worse instead of better, the proportion of marriages will necessarily decrease. Sterilization obviously is an answer to some of the problems which confront society in reference to the expense incidental to raising a family. Moral Aspect.—While it may be an open question whether sterilization will increase the proportion of marriages, there can be hardly any doubt as to its demoralizing effect, according to present ethical and moral standards of sex relations. Sterilization as a Substitute for the Abortionist.—Sterilization may prove to be a social factor which will greatly limit the present widespread practice of abortion. Relation of Sterilization to Illegitimacy.—Should sterilization supplant the abortionist as a social institution, it will be a saving factor for certain of the unborn. If the bastard child were the arbiter of its own destiny, it never would be born. Individual Rights versus State Rights.—The law to protect society against the criminal and other unfit classes by sterilization must soon logically be followed by laws to protect society against sterilization: such laws being in the way of regulation of the operation on "the fit."

AMERICAN JOURNAL OF TROPICAL DISEASES AND PREVENTIVE MEDICINE.

September, 1913.

Ameebe and Their Relation to Dysentery.—E. R. Whitmore sums up our knowledge of the intestinal ameebe of man by stating that there are two species: Entameba coli, a harmless commensal, found commonly in the intestinal contents of healthy men, and E. tetragesa, producing ulcerative dysentery. He maintains that the ameebe hitherto obtained in cultures from the intestinal contents and liver abscesses in man have nothing to do with the true parasitic ameebe. They are the free living ameebe found everywhere, and have gotten into the cultures as cysts that have been taken in with the food, or by contamination of the culture material in handling, or again, in some cases, through having taken up a parasitic or semiparasitic existence in the intestine.

Serums and Vaccines in Undulant Fever.—A. P. Hitchens refers to the fact that within the past two years cases of undulant (Malta) fever have been reported from Texas and Arizona, and reviews the attempts so far made to prepare serums and vaccines for use in the prevention and treatment of this disease. Some measure of success has attended the therapeutic use of vaccine. The B. melitensis seems, however, to have a special tendency to make for itself a nidus in the tissues and, as a consequence, offers resistance to the antibacterial powers of the blood, even if raised by specific treatment. An attempt is being made by the author to prepare a more efficient serum than has hitherto been produced. The bacteria are washed to free them from traces of the culture medium on which they have been grown, in order that very large doses may be given intravenously to horses without causing toxic or anaphylactic symptoms. Serum has been obtained which shows an agglutination titre of one to 2,000 and gives complete complement fixation with a melitensis antigen; but the practical value of the serum has not as yet been tested.

Cultivation of Malarial Plasmodia.—C. C. Bass and F. M. Johns, in a former paper, pointed out the necessity of adding dextrose to the culture material used for growing the Plasmodium falciparum in vitro. They now report that they were able to grow the organism in the blood (dehydrated) of a patient presenting both glycosuria and malaria, the sugar present in it evidently taking the place of that customarily added to the culture material. I. I. Lemann, in a clinical note on the same patient, states that the fever and malarial plasmodia persisted in this case in spite of an amount of quinine sufficient to control the usual case of malaria.

ANNALS OF SURGERY.

September, 1913.

Spinal Fractures.—Charles A. Elsberg believes that unless the patient's condition is so poor that any interference is contraindicated, an operation is called for when there is evidence that there is compression of the cord by bone or blood, or when there has occurred considerable contusion of the cord. Operation is indicated in all of these patients even if the symptoms of a cord lesion are not well marked; that is, there is only a partial loss of power below the level of the fracture, sensation is well preserved over considerable areas below the level of the lesion, many of the reflexes are preserved, the control of the bladder and rectum is little or not interfered with. In those patients with "incomplete" cord symptoms, an x-ray examination should be made as early as possible, in the patient's bds. and evidence of bone pressure thus obtained. A lumbar puncture should be done at once, for this will show whether there is a large amount of blood in the dural sac. If the x-ray fails to show any marked bony deformity, and the lumbar puncture reveals little blood within the dura, then it may be fairly certain that the symptoms are to a great extent due to a contusion of the cord. Contusion of the cord is soon followed by an edema of a very destructive nature or by bleeding into the spinal substance. The edema is very apt to cause, within a few days, a complete and irremediable transverse lesion of the cord, but its spread can be prevented by the decompressive effect of the laminectomy, to which may be added a direct incision into one of the posterior columns of the cord near the posterior median septum (Allen). A small collection of blood within the cord substance may be safely withdrawn by means of aspiration with a fine needle, and the formation of a hematomyselia cavity in the cord prevented.

The Hernial Sac in Its Relation to Concealed Intestinal Injuries.—Charles M. Remsen calls attention to the history of trauma applied to a hernial sac, followed by acute abdominal signs and symptoms: the tense rigidity of the abdominal walls in concealed abdominal ruptures; and the soft, tender, fluctuant and bulging hernial sac, an evidence of the escape of intestinal contents into this latter cavity. When coupled with the shock and general symptoms and signs which one would expect from such an injury, there is formed a group
almost positively indicating a concealed injury or rupture of bowel contained, at least at the time of the accident, in the sac which has suffered the trauma.

Subdiaphragmatic Abscess.—D. L. Despard says that if a mass presents in front, it should be reached through an abdominal incision without opening the general peritoneal cavity if possible, or if this danger cannot be eliminated, the peritoneum should be opened below the abscess and the general cavity be protected by gauze before evacuating the abscess. If the abscess is situated in the subhepatic fossa or is retroperitoneal on either side, it can be reached through a loin incision alone, or in conjunction with an abdominal incision through which the lower limits of the abscess can be determined and the dissection which is conducted through the loin incision aided and guided to the abscess without opening into the peritoneum. This accomplished, the abdominal wound can be closed by an assistant who has remained clean for the purpose. If there is reason to fear that the peritoneum may be entered in the effort to reach the abscess, the intraperitoneal site may be walled off from the general cavity of the peritoneum by gauze packs introduced through the abdominal wound. When the physical signs are well marked at either base the lung is apt to be displaced upward and the diaphragmatic and parietal layers of the pleura are frequently adherent, or in contact, so that they may readily be united. The transpleural operation is preceded by an exploring needle provided the operation is to follow at once, keeping in mind the danger of infecting the pleural cavity; this danger may be lessened by leaving the needle in place until the pleura is incised and, if necessary, the two surfaces united by sutures. The operation may be conducted in two stages, the first of which consists in resecting a rib, or ribs, and uniting the pleural surfaces and a day or two later exploring beyond these.

JOURNAL OF THE MEDICAL SOCIETY OF NEW JERSEY.

Psychoses Associated with Childbearing.—William C. Sandy bases his observations upon the study of fifty-two cases which seemed to have been definitely associated with pregnancy, the puerperium, or lactation. He finds that there is no one form of psychosis which is peculiar to these periods. Of the cases in his series over fifty per cent. belonged to the manic depressive type. Of these manic depressive cases, sixty-two per cent. began in the lactation period. Exhaustion delirium was the form in twenty-three per cent. of the series; three per cent. were infection deliria. Seventeen per cent. of the cases were of dementia praecox. From this it is obvious that a large proportion of the conditions of mental alienation occurring during childbearing are of favorable prognosis and end in recovery. About fifty-seven per cent. of the total number developed during lactation, and only fifteen per cent. during pregnancy. The average age of all the cases was just below thirty years. Seventy-three per cent. of the patients were multipare. Only five per cent. showed any distinct puerperal infection. In eleven per cent. there was more than one attack. Illegitimacy played a very minor role, there being but two such cases. Of the total number of cases, fifteen per cent. showed some hereditary influence. In no less than eighty-four per cent. the “make-up” of the patients seemed normal. There were only about five per cent. who could be considered actually inferior. In the six patients who had had more than one attack each, the etiological factors of the different attacks showed little in common, and it seems that the associated factors are quite as important etiologically, if not more so, than the mere childbearing state.

LONG ISLAND MEDICAL JOURNAL.

Diagnosis of Cardiac Disease.—Richard C. Cabot bases his remarks upon a series of 1,144 cases. Of this number only 425, or about a third, belonged to the rheumatic group and fifty-nine to the syphilitic group. There were 328 nonvalvular cases secondary to the effects of arteriosclerosis; 280 of the class known as kidney hearts; and forty-seven were associated with exophthalmic goitre. In 3,000 autopsies there was but a single case in which death was due primarily to mitral insufficiency; usually some other factor is present to account for the death and the valve lesion is but one feature of the picture. On the other hand, mitral stenosis caused death in eighty-one of the 3,000, and in a majority of these the diagnosis was made correctly during life. It has been said that mitral stenosis is commoner in women than in men, but in a total of 150 autopsies in which this lesion was found the sexes were divided equally. Like mitral insufficiency, aortic insufficiency is very seldom the cause of death, this resulting usually from other factors, the valve lesion being merely a concomitant phenomenon. Syphilis is the primary cause of ninety per cent. of the cases of this lesion, and is therefore the primary cause of death. In the nonvalvular cases, which comprise about two thirds of all cardiac cases, those due to arteriosclerosis predominate, followed closely in number by those secondary to renal lesions. In both there is an increased blood pressure, and the sphygmomanometer is the most trustworthy means for their diagnosis that we have. Cabot calls attention to the unreliability of the dial instruments, and recommends the mercurial manometers only. It is often difficult to determine whether the condition is due to arteriosclerosis or to interstitial nephritis, and it is, therefore, important to remember that the former condition is the more frequent in older persons, while the latter is the commoner in the young adult. Nephritis does not usually last so long nor begin so late in life as arteriosclerosis, and both uremia and anemia are commoner in nephritis than in arteriosclerosis.

SURGERY, GYNECOLOGY AND OBSTETRICS.

Management of Puerperal Thrombophlebitis.—P. Findley says that the Trendelenburg operation—ligating the thrombosed veins above the advancing clot—is surgically correct in theory, but
as a practical proposition it is a questionable procedure. The difficulties involved in the making of an accurate diagnosis before opening the abdomen are, as yet, insurmountable; furthermore, it is not possible to judge with accuracy the extent of the infection within the veins or elsewhere after the abdomen is opened. It is in direct violence to the rules of practice to traumatize tissues in the immediate neighborhood of a virulent infection. Furthermore, the risk of dislodging a thrombus in exploring the pelvic veins must be reckoned with. It is a physical impossibility to ligate all the veins leading from the genital organs, and, unless all channels are blocked there can be no assurance of checking the infection. The physical resistance of all cases of puerperal infection is far below par, a fact which should make one cautious in adding further to their burdens. We may rob them of the little resistance they possess. The writer believes that little dependence can be placed on serums and vaccines in these cases. Whatever may be the views on the question of ligation of veins or upon the administration of serums and vaccines, all agree that the body resistance must be supported by fresh air and nourishing food.

Iodine in Sterilization of the Skin.—Hunter Robb, performing a number of experiments on dogs, states that the older and more complex method of cleansing the skin gave eighty-six per cent. healing by first intention, while with the iodine technic only thirty-six per cent. showed perfect healing. From his experiments he concludes that there is still no certain method of sterilizing the skin: that tincture of iodine in all probability possesses a definite inhibitory action upon the growth of bacterial forms, and that sterilization with tincture of iodine is not to be relied upon, and should be used only when more elaborate forms of sterilization are contraindicated. To remove iodine alcohol is the most effective agent, for it has itself a distinct bactericidal power. Hyposulphite of soda forms with iodine the soluble sodium iodide, which may be washed off with sterile water. This works best when the solution is quite warm, but it is not as effective as a solution of potassium iodide. This substance in a ten per cent. solution can be thoroughly sterilized by boiling, and acts as a good solvent for the dried iodine. Later the surface is flushed off with sterile water.

Factors in the Formation of Skin Striations during Pregnancy.—F. J. Taussig states that only thirteen out of the sixty primiparé studied were free of skin striations. Skin striations occur most frequently at several points and usually make their first appearance about the sixth or seventh month of gestation. In girls under twenty years of age they are decidedly more pronounced and more frequently found than in older women. Obesity, particularly rapid increase in weight during pregnancy, predisposes to the formation of stric, especially those about the breast and thighs. Lack of abdominal support during pregnancy, as in those who wear no corsets, favors the formation of abdominal stric. On the other hand, tense and inelastic skin in which such stric are found is to some extent a factor in subsequent abdominal relaxation. At any rate, abdominal muscular relaxation and abdominal skin striation go hand in hand. Perineal tears have apparently no relationship to skin striation. In treating the condition the writer gives the following instructions to his patients: After a warm bath, moisten the finger tips in glycerin, pick up the skin in folds and gently rub it to and fro. Particular attention should be paid to the lower abdominal quadrants running from Poupart's ligament to the umbilicus. Over the hips and the breasts a similar light skin massage should be employed, the whole procedure lasting about fifteen minutes, every day. It is important that no deep pressure is exerted in this massage. The only reason for using glycerin in massaging the skin is that a lubricant makes the procedure less irritating and that glycerin is a clean and inexpensive lubricant.

An Operation for the Cure of Rectocele and Restoration of the Function of the Pelvic Floor. —George G. Ward has utilized the following operation for the past two years with uniform success: A gauze sponge on a spongeholder is inserted into the rectum as a guide. Short bullet forceps are caught at each posterior caruncle immediately below the orifices of Bartholin's glands, care being taken not to occlude them. A third forceps is attached to the posterior vaginal wall in the median line, marking the crest of the rectocele. Traction is made on these tenacula and the resulting triangle is outlined with a scalpel. This triangle represents the excess vaginal wall which is to be subsequently removed. By inserting the blades of blunt pointed scissors in the line of cleavage and opening them widely, the vaginal wall is entirely separated from the rectal wall from side to side and as high up as the culdesac of Douglas. The rectum having been completely mobilized, a catgut suture is passed through the vaginal wall in the median line as high up as possible in the region of the cervix. The suture is brought down and made to catch up the lower portion of the rectum and made to emerge through the vaginal wall in close proximity to its original insertion. When this suture is drawn up and tied, it obviously carries the dilated rectum up with it far beyond the limit of the subsequent resection of the vaginal wall. The rectocele having been disposed of, the excess vaginal wall which entered into the formation of the rectocele is cut away along the lines marked out with the scalpel at the commencement of the operation, and the cut vaginal edges are then sutured together with catgut. A pair of closed scissors are then passed through the fascia in the vaginal sulcus. They are opened widely, and withdrawn, thus making a large buttonhole which opens into the space in which lies the levator. The index finger locates the anterior edge of the levator and the muscle is caught with a pair of sponge forceps and drawn out of the buttonhole. The opposite muscle is secured in the same manner, and they are sutured together in the median line with chromic catgut. The outer edges of the fascial buttonholes are next sutured together over the approximated muscles with catgut. The operation is then completed by passing three or four silk-worm gut sutures from the skin surface behind the entire muscular approximation.
CLINICAL CONGRESS OF SURGEONS OF NORTH AMERICA.

GEORGE EMERSON BREWER, M.D., PRESIDENT.

The opening meeting of the fourth annual session of the congress was held at Orchestra Hall, Chicago, November 10, 1913, at 8.15 p.m.

Dr. E. W. ANDREWS, chairman of the committee of arrangements, welcomed the members of the association, after which he introduced Sir Rickman Godlee, president of the Royal College of Surgeons of England, who said that he had had the opportunity of seeing the work that was being carried on by the congress. He was impressed with the enormous amount of clinical material which he saw at all of the hospitals he had visited, and was greatly impressed with the methodical way in which instruction was carried on at these institutions.

Dr. MURRAY MACLENN, president of the Canadian Medical Association, congratulated the officers and members of the congress upon the remarkable success which had attended the organization from its inception. It was a happy circumstance that its membership embraced both the profession of the United States and of Canada. Medical science knew no territorial limitations. Canada might not care for reciprocity in trade, but she welcomed the closest associations and intermingling of the peoples of both countries. The progressiveness, the enthusiasm, broad views, broad education, well trained able minds, and skilled hands had all had their effect in placing American surgery on an eminently high plane. They in Canada looked to American surgeons and received freely from them much information, much suggestion, much instruction, and always accompanied with kindliness and courtesy.

Presidential Address: A Preliminary Report on a Simple and Rapid Method of Pyloric Closure in Gastroenterostomy.—Dr. GEORGE EMERSON BREWER, of New York City, reviewed the various methods of pyloric closure which had been suggested in the past: and referred to a series of experiments lately published by Taplina, showing that all simple methods of closure, as by ligature with or without contusion, the employment of a submucous plastic, a pedunculated seromuscular flap from the anterior abdominal wall, or closure by infolding suture, were not to be relied upon to bring about a permanent stenosis. Ligature by means of a strip of fascia taken from the rectus sheath, as suggested by Wilks, seemed to have better results; but in the opinion of the author, the only safe method was the unilateral pyloric closure suggested in 1885 by von Eiseleberg. This rather complicated operation could be relied upon to permanently exclude from the duodenum any stomach contents, but it had the disadvantage of being a difficult and prolonged procedure, often requiring from thirty to forty minutes for its performance. Doctor Brewer emphasized the fact that the present de l'editerat was for a method which could be as quickly and simply executed as simple ligature, and at the same time be as permanent in its results as the prolonged operation of von Eiseleberg. His method consisted in constriction of the pylorus by an aluminum band, which was easily passed around the tube at this point, and quickly rolled with the fingers into an unyielding ring with sufficient compression to obliterate the lumen of the tube, but not to compromise the vitality of the compressed tissues. Nine experiments upon dogs were reported, and the specimens thus obtained shown by lantern slides. From a study of these experiments, it was evident that this method of closure produced a complete occlusion of the pylorus, as proven by the fact that water would not pass the constricted point where the stomach was distended; and also by the fact that sections through the pylorus and aluminum ring showed by gross and microscopic examination, not only that the pylorus was closed, but that the vitality of the tissues was not impaired. A second series of experiments showed that the same method could be applied to the pyloric antrum, and also that the pylorus which had been closed for some months could have its function again restored by a second laparotomy and removal of the aluminum band. Although Doctor Brewer had not employed this method in the human subject, the animal experiments were so conclusive, that he believed it to be the simplest and safest method yet proposed for these cases.

Report of a Series of 156 Gasserian Ganglion Operations.—Dr. HARVEY CUSHING, of Boston, reported 156 cases of operations upon this ganglion with two fatalities. These fatalities occurred in the earlier cases. In 100 consecutive cases operated on there were forty-six males and fifty-four females. The neuralgia affected the right side in sixty-two cases; the left in thirty-six cases. Both sides were involved in two cases. He stated that it was the impression that these neuralgias occurred very much more commonly on the right side, but in the last fifty cases there had been an unusual number of left sided neuralgias which had brought the percentage up to thirty-six, whereas previously the ratio between neuralgias of the right and left sides was about three to one. Two of the patients operated on were eighty and ninety years of age respectively. The average age at operation was fifty-five years, the youngest twenty-six, and the oldest eighty-six. The average age at onset was forty-five years, the youngest eighteen years, the oldest seventy-four years.

Dr. JOHN B. MURPHY, of Chicago, said that two monuments should be erected to Doctor Cushing, one for his courage for leaving the promising field of general surgery and taking up the unpromising field of tumors and surgery of the brain, and one for his final achievement of success in this line of work. When Doctor Cushing reported 110 consecutive operations without a single death it was an achievement of which he and the medical profession of the world should be proud. The speaker had done twelve of these operations with four deaths. In the future he would not endeavor to remove the gasserian ganglion, but would adopt the method of extracting the root, which involved a little more work, a little more risk in the way of time and patience, but which gave splendid final results, as reported by Doctor Cushing.
Gastric Hemorrhage.—Dr. John B. Deaver, of Philadelphia, said gastric hemorrhage or the copious effusion of blood into the stomach was, as a rule, followed by hematemesis, and resulted from a number of disturbing factors in the mechanism of the upper abdominal circulation. In the minority of cases the blood was not at once ejected, but was passed subsequently by the bowel in the form of tarry stools. Cases of gastric hemorrhage fell into two groups, the surgical and the nonsurgical or medical. It was as great a mistake to operate on a nonsurgical case as it was to withhold operation in surgical bleeding. The exploratory operation, therefore, was not available for diagnosis, and successful treatment demanded a high degree of diagnostic skill in deciding for or against operation. Profuse and even fatal hematemesis without demonstrable ulceration of the stomach had been observed in a considerable number of cases, both at autopsy and at operation. Dieulafoy had described a variety of hemorrhages due to the formation of minute mucous erosions, single or multiple. Such erosions had been observed as linear or stellate fissures in the act of bleeding during the operation. Of 459 of their cases of upper abdominal disease, hematemesis occurred in only twenty-five per cent. of instances, and twenty per cent. of those cases were either simple ulcer or cancer of the stomach. A knowledge of the hemorrhagic possibilities of active congestion of the stomach could not be learned at the mortuary slab, but only by witnessing its bleeding surface in the living. Hemorrhage more or less acute might result from the formation of the typical acute peptic ulcer, the vessels beneath the muscularis mucosa being opened by the ulcerating process. Such hemorrhage was rarely fatal; the vessels opened were small and their walls soft and normal, permitting retraction and contraction with the formation of an oozing clot as the blood pressure was reduced by hemorrhage. In many cases acute ulcer announces its presence by bleeding and if appropriate measures were taken the hemorrhage was rarely dangerous and seldom repeated. While it was true that sudden massive hemorrhage did occur in chronic gastric and duodenal ulcer, it was also true that it was not a characteristic of ulcer to bleed profusely. Occult blood or small recurring hemorrhages were far more characteristic of ulcer, and it was, therefore, incumbent upon the diagnostican, in the presence of diffuse hematemesis, to adduce considerable evidence in the way of history or examination before concluding that ulcer was present. The hemorrhage due to malignant disease of the stomach, like that of ulcer, was not commonly profuse and sudden. In the early stages it was slight, even occult in the stools. It was more apt to be persistent than the hemorrhage of ulcer and tended to become progressively more marked. The hemorrhage from malignant ulceration was, as a rule, a slow seepage which gave rise to little systemic effect of bleeding, but revealed itself by the process of coffee ground vomitus or melena. Sudden hemorrhage was one of the modes of termination of gastric carcinoma, but in all but the rarest instances such an event was but the termination of an already established and evident malignant cachexia. During the past year there occurred in the practice of one of his Philadelphia colleagues a case of death from hemorrhage of an ulcerated myoma of the stomach. The growth was round, encapsulated, about six centimetres in diameter and its growth was chiefly inwards into the cavity of the stomach, much like a submucous myoma of the uterus. Operation might be indicated in gastric carcinoma when hemorrhage chanced to be an early symptom and there was still hope of cure; or it might be indicated in advanced or otherwise inoperable cancer when hemorrhage was so profuse and persistent as to shorten even the period of prognosis given to cancer. In this case the measures to be adopted were excision, gastrectomy, or jejunostomy, in accordance with the pathology found at operation. But four most essential questions remained to be settled: 1. The recognition of suitable cases; 2, the time to operate; 3, the type of operation to be performed; and, 4, the proof of our position by mortality statistics. The diagnosis of chronic eroding ulcer must be clear to warrant operation in acute gastric hemorrhage. Not only must the conditions which simulate it be considered and eliminated so far as possible, but we must be in possession of a history which pointed strongly toward the existence of chronic ulcer. The most important point was a history of long continued persistent painful indigestion definitely related to the ingestion of food. In reviewing the literature thirty-three cases of operation for acute gastric hemorrhage, exclusive of his own, were collected since the independent reviews of Tuffier and Connell in 1905. In those thirty-three cases there were eight deaths (24.2 per cent.). This was to be compared with Tuffier’s collective mortality of 36.3 per cent. in 1905, with Rodman’s mortality of 37.5 per cent. in 1901, and with Savariaud’s figure of 62.6 per cent. in 1898. It was easily seen that the mortality was becoming less, a fact attributable doubtless to various causes, but in part, at least, to increasing accuracy of recognition of the proper type of cases in which surgery was to be employed.

Dr. A. J. Ochsner, of Chicago, stated that we must not look upon gastric hemorrhage primarily as a surgical emergency. An idea which had permeated the surgical conscience, as a result of the surgical possibilities of the last few decades, had given the feeling that when any very serious condition arose, we must attack it surgically. This was true only when the good judgment of the surgeon indicated that the patient was in such a condition that surgical treatment would give the greatest possibility of cure. A careful and accurate diagnosis was the foundation for this judgment, based upon a thorough knowledge of the history of such cases. The actual death rate from chronic hemorrhages of the stomach was undoubtedly large and must be considered from the standpoint of ulcer of the stomach, and that treatment must again be based upon a diagnosis which now could be made with a great degree of certainty.

The Operation of Gastrojejunostomy and the Principles Which Should Determine Its Use.—Mr. Herbert J. Paterson, F. R. C. S., of London, said that there was little doubt that the immediate results of the posterior operation were better than
those of the anterior. The patients convalesced more smoothly, and vomiting was less common, while after the anterior operation it might be necessary to wash out the stomach once or twice during the first few days. As to the remote results, he was inclined to think that the advantage rested with the anterior operation. After the posterior operation some patients, few in number, it was true, after remaining well for months or years, began to suffer discomfort. In some instances this was due to a mechanical defect at the site of the anastomosis, such as a constriction produced by contraction of the mesocolon encircling the anastomosis. He was quite clear that the mesocolon should be sutured to the stomach a little distance away from the suture line, and not to the jejunum or to the suture line as was commonly taught. In other cases the defect was due to a kink produced by contraction of a dilated stomach, or to the formation of adhesions, or to rotation of the jejunum on its longitudinal axis during the process of sutting. For a good many years he had been advocating the view that gastrojejunostomy was a physiological one. Sir Berkeley Mynihan had expressed his belief that the "physiological explanation of gastrojejunostomy is rot." He would endeavor to give the reasons for his belief. First, in view of the allegation that gastrojejunostomy was a drainage operation, we must inquire, what was the effect of this operation on the evacuation of the stomach. His experience was that in cases in which there was no organic stenosis of the pylorus, the evacuation of the stomach was slightly accelerated. Usually the stomach was emptied in from three to four hours after a meal. Another means of comparing the motility of the stomach before and after operation was afforded by the study of the amounts recovered after a test meal. In sixty per cent. of a series of investigated cases the amount recovered after a test meal was less after operation than before, but the difference was not very great. In sixty-six cases the average amount recovered one hour after a test meal was 190 c. c. before operation, and 180 c. c. after operation. As a rule, when there was organic pyloric stenosis, the motility of the stomach was improved by gastrojejunostomy. He thought, therefore, we could conclude that in those cases in which the gastric motility was markedly impaired by pyloric stenosis or by adhesions, the operation resulted usually in a marked improvement in the evacuation of the stomach contents. In those cases, on the other hand, in which before operation the motility was unimpaired, gastrojejunostomy usually slightly hastened, but occasionally retarded, the evacuation of the stomach; but inasmuch as this retardation or acceleration fell within physiological limits, we were justified in saying that in cases in which, before operation, the motility of the stomach was unimpaired, the evacuation of the stomach was unchanged by gastrojejunostomy. Notwithstanding the absence of Gmelin's reaction in twenty-seven per cent. of his cases, he believed that the presence of bile in the gastric contents was a constant and very important feature after gastrojejunostomy. His reason for this statement was the observation that in ninety per cent. of his cases there was, after gastrojejunostomy, an increase of the mineral chlo-
rides in the gastric juice. This increase was not due to greater activity of the gastric mucosa because, as a rule, there was in seventy-five per cent. of his cases a diminution of the total chlorides. If this increase in the mineral chlorides was not the result of greater activity, it must be due to chlorides added from without to the gastric contents. For example, take the operation of appendicectomy, was there an increase in the mineral chlorides after this operation? In twenty-six per cent. of his cases of appendicectomy there was a marked decrease. In the remaining seventy-four per cent. there was an increase; but whereas after gastrojejunostomy the increase in mineral chlorides was accompanied by a decrease in the total chlorides, after appendicectomy the increase in mineral chlorides was accompanied, as a rule, by an increase in the total chlorides. After a gastrojejunostomy there was a constant increase in the mineral chlorides of the gastric juice. This increase must be due to chlorides added to the gastric juice by the entrance of bile and pancreatic juice; because, 1, the total chlorides of the gastric contents were diminished; 2, undoing gastrojejunostomy diminished once more the amount of mineral chlorides; 3, if an enterooanastomosis be performed the increase in the mineral chlorides did not occur; 4, in cases in which there was a marked excess of mineral chlorides; 5, as a rule, the increase in mineral chlorides did not follow operations other than gastrojejunostomy. Doubtless part of this increase was due to the neutralization of free hydrochloric acid and the consequent formation of sodium chloride. This did not affect his argument because, 1, this neutralization must be caused by the carbonates of the bile and pancreatic juice; 2, if, before gastrojejunostomy, free hydrochloric acid be absent from the gastric contents, there was still an increase in the mineral chlorides after gastrojejunostomy.

To his mind the conclusion was irresistible, that gastrojejunostomy was a physiological operation. It was easy to ascertain the changes in the gastric contents which followed gastrojejunostomy, but at present we must admit that we could only speculate as to which of those changes was the important factor in the relief of the patient. As he had already pointed out, a most striking feature after gastrojejunostomy was the diminution of the total acidity. The four practical lessons to be learned were these: 1, That the type of gastrojejunostomy employed is of less importance than the manner in which it is performed; 2, that if gastrojejunostomy be a physiological operation its use for the treatment of gastric hemorrhage is correct and explicable; 3, that occlusion of the pylorus is an unnecessary complication of gastrojejunostomy and is based on erroneous pathology; 4, that if gastrojejunostomy be a physiological operation, then it is as efficient a treatment for ulcers of the body of the stomach as for ulcers near the pylorus; in other words, gastrojejunostomy is preferable to excision.

Dr. Carl Beck, of Chicago, stated that Mr. Paterson was the father of the theory of the physiological effect of gastrojejunostomy, and what he had said in regard to the anterior and posterior operations, as well as the relative merits of each, was
very important and suggestive. As to whether pyloric exclusion was practically useless, further experimentation in the workshops of surgeons would determine. At present, surgeons could only take the say so of Mr. Parkison for it. As to the frequency of cancer of the stomach when ingrated upon ulcer, notwithstanding the authority of Kocher, he still believed that the authority of the pathologists at Rochester was just as good, and their proof just as convincing as the pathological reports which had emanated from the laboratory of Kocher.

(To be continued.)

Letters to the Editor.

CORRECTION.

173 Lexington Avenue.
New York, November 16, 1913.

To the Editor:

I shall thank you for correction of the typographical error in my letter Kymograph and Kymogram published in your esteemed Journal of November 15th, namely "dam" instead of "darn." A. Ross, M.D.

AMORPHOUS PHOSPHORUS IN SENILE ARTERIOSCLEROSIS.

611 East 68th Street.
New York, November 13, 1913.

To the Editor:

The author has used the red amorphous phosphorus in senile arteriosclerosis for several years. Given originally as a substitute for ordinary phosphorus in senile debility, it was found that it was eliminated as amorphous phosphate of lime and that the lime elimination was thereby increased. Weil's experiments showed that the lime elimination in arteriosclerosis was diminished. Phosphorus has the property of combining with lime and increasing the lime assimilation. In the small doses which can be given when the ordinary phosphorus is employed, the phosphorus will combine with the lime of the food and increase the amount of lime salts in the body. When given as amorphous phosphorus the dose is two grains or more several times a day, and with a lime-free diet, the lime required for the combination necessary to secure the elimination of the phosphorus excess, is drawn from the abnormal lime deposits. This appears to be the rationale of the treatment and explains the good results obtained from its use.

TOUCH DISEASES.

New York, November 16, 1913.

To the Editor:

It remained for a few fortunate physicians to discover what our masters in medicine, past and present, have overlooked.

No one till just lately ever I new that there were actual diseases and "touch" diseases. One hears now the following diagnosis: A touch of the grippe, a touch of bronchitis, a touch of asthma, a touch of pneumonia, a touch of consumption, a touch of appendicitis. It would seem that in one case the pathogenic organisms cause the grippe, bronchitis, pneumonia, consumption, and appendicitis, while in the other case the organisms just touch the part, and before they have time enough to cause a real pneumonia or consumption they are frightened away by the doctor. Is there anything more absurd? A physician with any respect for himself and his profession surely feels disgusted at this new medical nomenclature.

J. Epstein, M.D.

CONCLUSIONS OF FREUDIAN SCHOOL.

1517 South Kenzie Avenue.
Chicago, November 14, 1913.

To the Editor:

In view of the fact that the Journal, for November 8th was on the press before you received the revised and corrected proof of my paper entitled "If Certain Conclusions of the Freudian School Were True," which appeared in that issue of the Journal, the article as published contained a number of errors and omissions, some of which are so important that, although they will all be checked up in the reprints, I feel that the attention of your readers should be specifically called to them.

On page 914 "practically always" on line 7 should read "usually"; "the dreams" on line 12 should read "most of the dreams"; "all the dreams" on line 13 should read "most of the dreams"; "every possible mental state" on lines 18 and 19 should read "almost every possible mental state"; "not a thought" on line 20 should read "hardly a thought." On page 915 "always of sexual etiology" on line 46 should read "always of sexual etiology, when the condition is of primary origin." On page 916 "psychobiological basis" on lines 24 and 25 should read "psychobiological basis."

May I ask that you publish this letter in your columns?

Meyer Solomon, M.D.

Book Reviews.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think your readers are likely to be interested.]

The second edition of this work, the first edition of which, the author tells us, has been exhausted within one year, embodies the most notable achievements of the last twelve months. This statement means much to those who are familiar with the vast amount of work done in the study of infection and immunity throughout the realm of experimental medicine. In physiological chemistry alone, for example, which is but a subdivision of the subject in the author's annual aggregate, we have annual report to thousands! Besides, the author has adds sections on autotherapy and normal serum therapy, on the chemotherapy of pneumococcus infections and of cancer, and on the serum diagnosis of pregnancy. We bespeak for this new edition the same kindly reception accorded its predecessor.

The author of this work on Gynecology appreciates the point that an excess of descriptive detail might induce one not properly drilled and apprenticed in surgical technic to make the difficult operation and experience in this way become a source of possible danger. Still the book is marked by that very minuteness of detail and wealth of illustration which one finds lacking in most treatises of this kind. Individuality has been repressed, the actual status of each subject at the time of writing seeming more important to the author.

The surgical aspects of gynecology are well considered, the working details of over two hundred operations being given. Many of the sketches of the more than four hun-
dred illustrations were made in the operating room, not a few by the author himself. The book is wholly intended ed and the effort the author has expended all his best efforts. This volume is well worthy a place on the practitioner's table along with his best reference and working books.

The White Linen Nurse. By ELEANOR HALLLOWELL ABBOTT. With Illustrations by HERMAN PFEIFFER. New York: The Century Company, 1913. Pp. 276. (Price, $1.50.) One of the most charming novels we have read lately is The White Linen Nurse, the first book of a physician is the book before us. It contains a charm which hardly a reader, if he is a physician, can escape. A young Canadian girl arrives in New York with the intention of becoming a nurse. The girl enters the leading surgeon, a man over forty, whose first marriage was a union of convenience, and proved a failure. It left the surgeon with a child whom he loves dearly but to whom he is unable to give the necessary care. Nurse and surgeon are thrown together, and a marriage follows with an ending which should satisfy everybody.

A Manual of Otology. By GORHAM BACON, A. B., M.D., Professor of Otology in the College of Physicians and Surgeons, Columbia University, Aural Surgeon, New York Eye and Ear Infirmary, etc. Sixth Edition, Revised and Enlarged. With 164 Illustrations and Twelve Plates. New York and Philadelphia: Lea & Febiger, 1913. Pp. 536. (Price, $2.25.) The necessity for the sixth edition of this valuable little manual bespakes the popularity which has been accorded it. The revision of the text has been, as far as permitted in the limited space of a manual, in accordance with the rapid strides which have been made of late in this branch of medicine. The description of the anatomy of the labyrinth is unusually clear and comprehensive for such a small book. The portion relating to suppurative labyrinthitis and the submucous resection of the nasal septum have been wholly rewritten and somewhat enlarged, while the subject of otosclerosis has been considered important enough by the author to be recast. The significance of vaccine therapy and the early examination of the cerebrospinal fluid in leptomenigitis is only emphasized while attention is called to the modern excision of the tonsils. The cuts throughout are unusually clear, instructive, and are invariably accompanied by a concise, elucidating description. A continuation of the popularity shown earlier editions is justified for this one.

Military Hygiene and Sanitation. By Colonel CHARLES M. MEULVILLE, M. B. EDIN., D. P. H., Royal Army Medical Corps, Professor of Hygiene, Royal Army Medical College, Member of Council, Royal Sanitary Institute. With Diagrams. New York: Longmans, Green, & Co.: London: Edward Arnold, 1912. Pp. vii-418. (Price, $2.50.) We have been tardy in the review of this unique and valuable work for several reasons. We were forced to read it through and through, finding it so interesting and at the same time so entertaining, that we could not call a halt until the entire, really classic unit had passed in review. Having read the volume, much time was required for inspection and retrospection. Favorable comment and justice due would demand that we quote pages of our author's experience. To be appreciated this work must be read with the examining officer in mind. The examining officer is aptly and pertinently defined, especially for younger medical officers. "The duty of the military sanitary officer in time of war, is, like that of every other individual in the army, to defeat the enemy. The price of success in war is human life and suffering, and it is for the commander to decide on the terms of payment. He may decide to pay the price in exhaustion and disease, or in terms of bayonet and gun-shot wounds. He will choose the latter, if this method of payment which seems to him the most convenient and the cheapest, but in any case the choice rests with him, and not with the medical authorities." His definition of military sanitation is the most prominent, "Sanitation is the art of removing certain clothes in a certain manner; carrying a certain load, disposed on the body in a certain manner; as one unit in a body of men; at a pace regulated by the average physical conformation of that body, and not by the personal peculiarities of any particular individual." He adds, not the forceful language! "The greatest enemy on the march is heat. Water on the march should be treated with as much care as ammunition. Water discipline is as essential to good marching as fire discipline is to good fighting!" Furthermore, he must consider the question of walking as it affects the foot plus a boot, and we must make the best of it. This is to a great extent a disciplinary measure. The chapters on Food and Dietetics and The Soldier's Ration, bristle with facts and up to date practical and logical suggestions, and Field Service Rations, covers all that is worth knowing on the subject and his opinions are "gospel truth." About the Purification of Water, he goes into detail and considers all methods to date, and remarks, in concluding, of filtration or chemical purification: "If germs are not removed from water by filtration they may be killed in the water, and this is done either by light, heat, or chemicals. Light is used in the form of the ultraviolet rays. Undoubtedly we have in sterilization by ultra violet rays the most promising method yet put forward."

His methods of Disposal of Waste Matters in the Field are most interesting and his experience is exactly the same as that of our own United States Army sanitary officers. He urges incineration, the use of oil or lime and he places reliance on the use of some strong smelling chemical obnoxious to the fly. He looks on an efficient system of latrine and urinal construction and management as being the keystone of practical sanitation in the field. Generally speaking, makeshift sanitation is a mistake and apt to cause friction, but when a crisis occurs, as an epidemic of infectious disease, the medical officer must take personal charge of the situation. If the private soldier sees that the medical officer considers the special rules he has made regarding efficient importance for him to sacrifice his own comfort and leisure to insure their efficient observance, that astute individual will accord to those rules a respect, which, in course of time, he will probably extend to the rules, and the methods of the examination as well. To the exanthema we are disappointed that he makes no reference to measles nor does he condemn the use of straw in filling bedding sacks or on the picket line. As to the chapter on Disinfection the author's experience coincides with ours, especially as the best chemical one of the phenol group, after incineration and boiling. This book ought to be found in every medical library. It appeals especially to every man in the Reserve Medical Corps of the United States Army. For all medical officers in the service of the United States, regular army, or national guard, especially to the younger officers, it must prove a boon companion.

Meetings of Local Medical Societies.

MONDAY, November 21st.—Medical Society of the County of New York (annual).

TUESDAY, November 22nd.—New York Academy of Medicine (Section in Laryngology and Rhinology); New York Dermatological Society; New York Psychoanalytical Society; Metropolitan Medical Society of New York; New York Medical Union; New York Otolological Society (annual); New York City—Riverside Practitioners' Society; Valentine Mott Medical Society, New York; Women Physicians of New York; Alumni Association of Seney Hospital, Brooklyn; Rome, N. Y., Medical Society; Buffalo Academy of Medicine (Section in Pathology).

WEDNESDAY, November 23rd.—New York Surgical Society (annual); New York Society of Internal Medicine; Medical Union College, New York.

THURSDAY, November 24th.—New York Physicians' Association; Bronx Medical Association; New York Celtic Medical Society; Hospital Graduates' Club, New York.

FRIDAY, November 25th.—New York Academy of Medicine (Section in Obstetrics and Gynecology); Academy of Medicine; Manhattan Medical Society of German Physicians; New York Clinical Society; Manhattan Medical Society; Italian Medical Society of New York; Hospital Graduates' Club, Brooklyn; Aubudon Medical Society, New York.
United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending November 15, 1913.

Earle, Baylin H., Passed Assistant Surgeon, Detailed to proceed to Anacortes and Hoquiam, Wash., and make inspection of these ports relative to quarantine matters and medical relief of seamen. Frost, W. H., Passed Assistant Surgeon. Detailed to attend a meeting of the Board of Control for Rivers and Waterways, to be held at Chicago, Ill., on November 11 and 12, 1913. Glanville, W. E., Assistant Surgeon. Relieved from duty at Ellis Island, N. Y., and detailed to the direction of the Laboratory for temporary duty, under Surgeon L. L. Lumsden, in making a sanitary survey of Berkeley County, West Virginia. Goldberger, Joseph, Surgeon. Directed to proceed immediately to Rochester, N. Y., for the purpose of investigating certain cases of suspected typhus fever. Gutierrez, Castro. Acting Assistant Surgeon. Detailed to attend the Sixth Pan-American Medical Congress at Lima, Peru, November 9, 1913. Hasseltine, H. E., Passed Assistant Surgeon. Detailed to inspect the stations of the Port of Dania Island, Wash., for the purpose of making an inspection of the United States Penitentiary at that point to ascertain what improvements, if any, should be made in the sanitary condition of the premises. Johnstone, W. H., Assistant Surgeon. Directed to proceed to Seattle, Wash., and report to the commanding officer of the Revenue Cutter *Tahoma* for temporary duty on special relief work in Alaskan waters. Lloyd, B. J., Surgeon. Detailed to investigate cases of boisterous bark *Dundee* arriving at Bellingham, Wash., from Finland. Lumsden, L. L., Surgeon. On the request of the State and local authorities, directed to undertake a systematic investigation of typhoid fever in Berkeley County, W. Va., E. E., Passed Assistant Surgeon. On the request of the State Department of Health of New York, detailed to attend the annual conference of health officers of the State to be held in Utica, N. Y., on November 19 to 24, 1913. Parker, H. B., Passed Assistant Surgeon. Relieved from duty at Guayaquil, Ecuador, effective November 15, 1913, and continued on duty at Ellis Island, N. Y. Phelps, Earle B., Professor. Detailed to attend the meeting of the National Association for the Protection of Rivers and Waterways, to be held in Chicago, Ill., on November 11 and 12, 1913. Robertson, H. McG., Passed Assistant Surgeon. Directed to assume temporary charge of the Service at Philadelphia, Pa., from November 8 to 14, 1913, in addition to present duties, until officer is assigned permanently to the station. Schercheswsky, J. W., Surgeon. Detailed to attend the Fourth Annual Meeting of the American Association for the Study and Prevention of Infant Mortality to be held in Washington, D. C., November 14 to 19, 1913. Stimpson, W. G., Surgeon. Relieved from duty at Philadelphia, Pa., and directed to report at the bureau, Washington, D. C., on November 14, 1913, for duty. von Ezzor, R. H., Surgeon. Detailed to represent the Service at the annual meeting of the Southern Medical Association, to be held at Lexington, Ky., November 18 to 20, 1913, reporting at the bureau en route.

United States Army Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Army for the week ending November 15, 1913:

Baker, David, Major, Medical Corps. Joined Port Sill, Oklahoma, on November 6th. Bevans, J. L., Major, Medical Corps. Left for leave. Bradley, A. E., Lieutenant Colonel, Medical Corps. Ordered on an inspection trip from Philadelphia, Pa., to Fort Monroe, Virginia. Castlen, C. R., First Lieutenant, Medical Corps. Joined his station, At Fort Riley, Kansas. Clemens, A. H., First Lieutenant, Medical Corps. Granted twelve days' leave of absence. Lyster, W. J. L., Major, Medical Corps. In addition to his duties in the Army Medical School, Washington, D. C., is assigned to duty in the surgeon general's office. Magee, James C., Captain, Medical Corps. Is detailed as a member of the examinatory board at Fort Leavenworth, Kansas, appointed in paragraph 4, Special Orders No. 246, October 21, 1913, War Department, vice Captain Thomas D. Woodson, Medical Corps, who is relieved. Porter, R. S., Captain, Medical Corps. Joined the Second Division, Texas City, with Fourth Field Artillery. Woodward, T. D., Captain, Medical Corps. Ordered to accompany Second Squadron, Fifteenth Cavalry, from Fort Leavenworth, Kansas, to Fort Bliss, Texas, about November 7th.

Married

Cummings—Groh.—In Philadelphia, on Wednesday, November 12th, Dr. Michael P. Cummings, of Reidsville, N. C., and Miss Bessie Groh. Grainger—Costa.—In Charleston, on Wednesday, November 13th, Dr. Henry H. Grainger and Miss Jessie J. Costa. Monahan—Thompson.—In Somerville, Mass., on Wednesday, November 12th, Dr. Edward J. Monahan and Miss Olive Thompson. Warncke—Chun.—In Elizabeth, N. J., on Wednesday, November 13th, Dr. Frank Hermann Warncke and Miss Blanche Chunar.

Died

Boul.—In Honeoye Falls, N. Y., on Friday, November 7th, Dr. Charles E. Boul, aged forty-five years. Cameron.—In North Yakima, Wash., on Thursday, October 30th, Dr. John M. Cameron, aged fifty-three years. Colburn.—In Utica, N. Y., on November 6th, Dr. Carl A. Colburn, aged seventy-three years. Carroll.—In Albany, N. Y., on Sunday, November 9th, Dr. Terence Lathrop Carroll. Clements.—In New York, on Thursday, November 13th, Dr. A. J. Clements, aged eighty-one years. Davis.—In Pittsburgh, Pa., on Friday, November 7th, Dr. Frank M. Davis, aged forty-five years. Denner.—In Paterson, N. J., on Friday, November 14th, Dr. Edward F. Denner, aged forty-one years. Engel.—InTryon, N. C., on Tuesday, October 28th, Dr. William Royal Engel of Charlotte, aged thirty-five years. Fennell.—In New York, on Thursday, November 6th, Dr. Thomas C. Fennell, aged forty-eight years. Hall.—In Memphis, Tenn., on Monday, October 27th, Dr. Joseph Hall, aged sixty years. Higbee.—In St. Louis, Mo., on Monday, November 3rd, Dr. Edward H. Higbee, aged sixty-six years. Hill.—In Baltimore, Md., on Monday, November 10th, Dr. J. Harvey Hill, aged seventy years. Homan.—In Everett, Mass., on Wednesday, November 5th, Dr. John Milton Homan, aged thirty-nine years. Jenkins.—In Kilbourn, Wis., on Monday, November 3rd, Dr. George V. Jenkins, aged ninety years. McCarrell.—In Washington, Pa., on Monday, November 3rd, Dr. James McCarrell. McClelland.—In Pittsburgh, Pa., on Saturday, November 15th, Dr. James H. McClelland, aged sixty-eight years. Miller.—In Pittsburgh, Pa., on Friday, November 14th, Dr. Zaimack Taylor Miller, aged sixty-eight years. Musgrave, N. C., on Friday, November 7th, Dr. Garley D. Musgrave, of Mount Pleasant, aged thirty years. Mullin.—In Philadelphia, on Thursday, November 13th, Dr. William Wellington Mullin, aged fifty-two years. Murray.—In Toronto, Canada, on Thursday, November 6th, Dr. Charles Stuart Murray, aged sixty-three years. O'Neill.—In Long Beach, N. Y., on Thursday, November 13th, Dr. Simon J. O'Neill of New York, aged fifty-two years, extended on leave. Somerville, N. C., on Thursday, November 6th, Dr. Leandre Coyteux Prevote, of Ottawa, Canada, aged sixty-three years. Stewart.—In Curtis, Neb., on Saturday, November 13th, Dr. Charles Riker Stewart, N. C., on Thursday, November 13th, Dr. John S. Walker, aged sixty-six years. Williams.—In Ridgway, Pa., on Saturday, November 8th, Dr. Walter L. Williams, aged sixty-nine years.
THE CURE OF ATAXIA.

By William J. M. A. Maloney, M.D., Ch.B.,
F. R. S. Edin.,

New York,
Adjunct Professor of Diseases of the Mind and Nervous System,
Post Graduate Medical School; Attending Neurologist,
Neurological Hospital.

GENERAL CONSIDERATIONS.

In tabes, ataxia has two components, a physical component—the characteristic structural changes occurring in the peripheral, spinal, vestibular, and cerebellar parts of the neuromuscular mechanism which subserves coordination; and a psychic component—the changes in the psychic control which has been gained by education over reflex movements in order to permit voluntary action. These structural lesions and those psychic changes tend to incoordination. At any moment the tendency to ataxia, or coefficient of ataxia, must be equal to the ratio between the incoordinating tendencies or complexes and the actual coordinating power.

Coefficient of Ataxia = \frac{Ataxic influences or complexes}{Actual coordinating power}

The ataxic influences or complexes thus comprise organic structural changes and functional psychic derangements. The actual coordinating power depends upon the inherent cerebral capacity, upon the training in the function of coordinated movement, and upon the nutritional and morbid alterations which the brain has undergone.

When this ratio equals unity, the ataxic threshold is reached; when it is less, coordination persists; when greater, ataxia is evident. To cure ataxia we must reduce this ratio below unity. We must diminish the numerator, the ataxic complexes; and increase the denominator, the actual coordinating power. The combating of the physical element, the structural changes, in the ataxic complex is rarely attended with such success. I wish here neither to dwell upon the causes of this customary failure nor to discuss the relative merits of the various remedies against the emasculated, and often more or less innocuous Spirochetæ pallida detectable in tabes, and therefore blamed both for the banal syphilitic proliferations which it does cause, and for the primary tabetic degenerations which it does not cause.

Apart from the removal by medicinal means of the syphilitic tissue overgrowth which in the meninges may impair function without producing permanent destruction of the entering and emerging reflex paths, it is doubtful if we can by any measures directly affect to an appreciable extent the reflex mechanism in the spinal cord. Experiments upon the spinal reflexes of animals in which by transpositions and graftings the reflex paths were altered, showed that some influence may be exerted, that a readaptation, reeducation, can occur, even at the level of the spinal segment. But this influence is slight, slow, and uncertain. Efforts to relieve ataxia by way of the physical component, in spite of the knowledge which Sherrington Head and others have given us of it, are therefore not likely to be much rewarded. The tremendous influence which can be wielded through the psychic component has long been known. Indeed, a physician recently reported to me a case in which a faith healer cured severe ataxia when more customary methods in the hands of several physicians had failed. Ataxia, once it is established, comes to be among the readiest of the emotional expressions of unpleasant states in the tabetic. Anger, grief, fear, fatigue, depression, all increase ataxia. All are externalized partly as an increase of the ataxia. Ataxia is, in the ataxic tabetic, in part, an emotional expression. One of the chief elements in the psychic component of ataxia is fear. The attitude of the typical ataxic is partly a motor expression of his fear. His broad base, his constant use of a stick, his small steps, his gaze fixed on the ground, are all partially fear affects. So also are the curious muscular contractions which he acquires and perpetuates in his attempts to balance.

Fear is one of the most potent causes of ataxia. The effect of fear upon ataxia is evident in every ataxic. Practically every ataxic walks better in private than in public; his fears increase at the slightest provocation; he dreads open spaces, changes of level, street crossings, traffic, et c.; and as he dreads, his ataxia increases. I have recorded instances where fear alone increased the value of the ratio in our guiding formula above unity and precipitated a patient from the preataxic into the ataxic stage. Just as fear increases ataxia, so reassurance diminishes it. We can therefore reduce the numerator of our ratio, we can reduce the force of the psychic complex of ataxia, we can reduce the value of the coefficient of ataxia and decrease ataxia, by alleviating fear.

Since the dawn of intelligence, man has known that practice perfected movement. Leyden, Goldschiöder, and the Swedish school of gymnasts showed that what prevailed in health did not cease in disease; that movement was most excellent therapy in all morbid conditions wherein the function of movement was disturbed. Frenkel, since 1897, has
done much to organize and to popularize this movement therapy in the cure of the ataxia of tabes and the service which he has rendered is acknowledged in styling the movements, Frenkel's exercises.

The importance of fatigue we have long known, but it has of late years received a new and exaggerated value from the excellent work and writings of Edinger.

We are still ignorant of all but these crude facts regarding the psychic mechanism of progression; but that removal of fear, emotional control, relief of fatigue, and educational exercises are strongly indicated in the psychic treatment of ataxia, is incontrovertible. By these measures we may diminish the psychic component of ataxia, and increase the coordinating power also; we may, therefore, diminish the value of the coefficient of ataxia; and if the diminution brings the coefficient below unity, we may restore a patient to a condition of outwardly perfect coordination.

The faith healer removed fear alone, and ataxia disappeared. Electricity, massage, hydrotherapy; glandular extracts, lecithin, and other organic substances; practically every inorganic substance in the pharmacopeia; suspension, chiropractic, and osteopathic manipulations; and treatment by local irritations and other manoeuvres, all have cures to their credit. All doubtless contain elements which confer benefit. Mechanical and chemical agents may produce advantageous nutritive effects upon both nerves and muscles. But the efficiency of these measures depends mainly upon the administrator. A physician can incite hope by any treatment, and hope begets courage. Every treatment the efficacy of which depends mainly upon the personal reaction of the patient to the physician is limited in its usefulness mainly to the sphere of the physician who believes in it. Only when therapy is directed against the essential cause of a symptom can improvement be expected from the hands of all physicians. Even then the improvement will vary; even then the personal reaction will markedly influence the result. But when the personal reaction is slightest the intrinsic value of the treatment remains, and improvement still ensues.

The only treatment which so far has proved of universal value is that which Frenkel has popularized. This treatment by educational exercises mainly tends to increase the denominator of our guiding formula, to increase the actual coordinating power. The influence which it has upon the numerator is merely that due to the reduction of fear which follows the diminishing of ataxia and which confidence in the treating physician inspires.

In my hands the Frenkel system did not yield results as good as I desired; so far as I can judge from personal observation, in the hands of others it also falls short of what one would wish to attain. There are few cases which do not improve to any degree by the Frenkel method. There are equally few which improve to a degree that permits unaided walking in public. Complete failure is exceptional. Indeed if some degree of improvement is not attained it may be more the fault of the physician than of the method.

But, as a rule, the Frenkel system achieves only partial success. The Frenkel treatment may achieve more in special cases such as some of those who develop acute ataxia from psychic causes, some slight cases, and some cases with indomitable will and unceasing persistence. It may also achieve more in the hands of the few who are as Frenkel.

It is illogical to criticize a system for the failures of its disciples. But no system of therapy is harshly judged from its average results. The system which is only satisfactorily efficient in the hands of the few is a system which lacks what only these few can provide, and to that extent is an imperfect system.

Frenkel insists upon the control of movement by vision as indispensable to success. The patient must follow every movement visually. That an elaborate training should be conducted by the aid of the visual mechanism—a mechanism which may be implicated in the disease—and that patients should depend on sight when vision may be complicated by ptosis, ocular palsies, ataxia of the ocular muscles and optic atrophy, is not so irrational as it seems.

The main function of the vision, I believe, in this process of reeducation is not the directing of movement, but the directing of attention, or rather the directing and limiting of attention, to movement. Frenkel, so far as I know, does not admit this.

The value of visual fixation as a prop to attention is a matter of common knowledge. The partially deaf who are misguided taught lip reading often improve in hearing thereby. We usually fix our attention by looking while we listen, or feel, or smell. But to concentrate our attention to the utmost degree in listening or in smelling, we close our eyes. To devote our whole attention to muscular sense impressions we ought also to close our eyes. Physicians have more or less recognized that for over thirty years, Frenkel himself says: "Blindness. In this connection we have to mention two interesting facts which have not yet been sufficiently explained, namely, that tabetics who lost their sight at an early stage of the disease seldom developed much ataxia and, that developing blindness is accompanied by a marked improvement in the ataxia already present."

It seemed to me, from clinical and experimental evidence, to be a law that of two tabetics at any stage of the disease, one blind, the other seeing, other things being equal, the blind is less liable to be ataxic—more liable to persistently coordinate. Therefore the use of sight during the training is a hindrance not a help to coordination. The principle underlying the improvement in ataxia which results from blindness may be crudely stated as follows: The less vision monopolizes attention, the less the distraction, the more perfect the discrimination of sensations from other spheres. The sphere in which the ataxic needs enhanced perception is the sphere of the muscular sense impressions. Blind tabetics teach us, and the personal experiences of Doctor Wachsmann and of myself, have recently proved clinically, that the way to teach ataxics to perceive their residual muscular sense impressions, is to eliminate vision. Movement should not therefore be taught as Frenkel teaches it; the patient should not be directed to follow every movement with his gaze; he should be taught to move blindfolded.

Chesterton when he defined a pessimist as one who looks at his feet, was telling in jest a truth the
importance of which cannot be overestimated. To make vision an essential guide to movement is to make a visual automaton out of a man, and to lay the foundation for an anxiety neurosis. For if he is taught not to move unless he looks, he soon fears to move unless he sees, and then fears everything that he does not see. The vicarious and unnecessary use of vision by ataxics is, I think, one of the most fruitful sources of the fear from which tabetics suffer, and which so greatly disturbs their coordination. An ataxic should be taught to move blindfolded, first, because of the greater ease with which he can thus be taught; secondly, because no gross movement visually controlled can ever be anything but awkward; and thirdly, because of the serious handicap which the necessity of sight imposes upon movement. I would insist upon the value of blindfolding from the very beginning of the exercises, from the first lesson.

The Frenkel treatment takes practically no cognizance of the effect of fear upon ataxia. By using visual control in the movement exercises it handicaps the patient in the speedy and perfect acquiring of movements, and it may actually engender and perpetuate fear which tends to increase ataxia. The typical straddle-legged, artificially supported, contorted attitude of a man consumed with anxiety is the usual result. I wish to state that in making these remarks I do not aim to disparage the Frenkel treatment, but merely to explain why I sought some more effective means of treating this distressing symptom, ataxia.

While I was a house physician at the National Hospital, London, I was disappointed in the degree of improvement which ambitious, intelligent ataxics attained by the Frenkel system. The fact that the blind tabetic was less ataxic than the seeing, at least, in part because of his blindness, led me later to teach ataxics to move blindfolded. Improvement occurred more rapidly than when they were taught without being blindfolded.

After observing how fear increased ataxia, after encountering two cases which I have since published in which fear was the immediate inciting agent of the ataxia, and after finding from literature and report that such cases were not infrequent, I added to blindfolding certain measures to alleviate fear. The method of curing ataxia which I now practise has been gradually evolved from these two basal considerations,—the concentration of the attention by blindfolding during the coordinating exercises and the elimination of fear.

**TECHNIC OF THE TREATMENT OF TABETIC ATAXIA.**

The patient is not informed about his disease, or its cause, and is reassured regarding its course. He is thus spared much mental anguish. Appropriate measures are taken for information regarding the activity of the original infection and the usual medical treatment is instituted.

**Mechanical Measures.**—Ataxia itself is a fertile source of fear. If we relieve the ataxia we, to that extent, relieve fear. To attempt to mitigate ataxia and fear, for the one hour every second day that the patient spends in the physician’s office, and during the other forty-seven to allow a whit more staggering than is unavoidable, is seriously to handi-
cap treatment. For this reason I begin the treatment of ataxics who are not bed or chair ridden by utilizing simple mechanical aids to minimize ataxia when walking. A high shoe or boot, specially strengthened with leather on the outer side of the ankle, increases the support at the ankle and prevents the foot turning in. The heel is low, wedge-shaped, the base of the wedge being on the ground, and is continued along the outer side of the shoe. A steel plate (in the beginning in severe cases) placed in the sole to prevent bending. The shoe should be as light as is consistent with maintaining its shape. When the shoe is on the ground it rests with its whole bearing surface. The patient gets support from every part of this broadened surface simultaneously. He does not oscillate every time he puts his foot down. He feels more secure. He is more secure. He is readily weaned from the straddle legged attitude which is so disconcerting to coordinate walking. As he feels more secure, he feels less, and the psychotherapy of the physician does not cease with the medical visit. Most tabetics have faulty arches. Appropriate arch supports are of the greatest value. The first step in treatment is to minimize the mechanical disabilities of the ataxic. The occasional sudden “giving” at the knees and ankles has a very demoralizing effect upon ataxics. The “giving” is mainly due to the loss of muscular tone, but may partly arise from the overstretching of the hypotonic muscles inducing the reflex, umkehr, contraction. To avoid the “giving,” I lightly support the knees by a bandage of elastic webbing.

**Blindfolding and Relaxations.**—The patient is made to lie down, blindfolded. He is enjoined to dismiss all thoughts of extraneous affairs, to allow his mind to tranquilize, and to attend strictly to what he is told. The room is maintained as quiet as possible to avoid distracting him. He is then ordered to relax the muscles first of his face, then of his neck, then of his trunk and then of his limbs. Each order is repeated and restated, first alone, and then linked with the preceding order. The whole process is conducted slowly and with suitable pauses. From these relaxation exercises, practised blindfolded, three results are attained: First, ineffective, often useless, and sometimes completely disconcerting muscular contractions which have been acquired in attempts to balance, are got rid of so that the coordinating exercises can be begun on an unstrained musculature and not superimposed upon existing habit contractions. Secondly, active relaxation confers a great training in attending to muscular sense impressions. Thirdly, the patient becomes less fearful and more receptive because, in so far as fear is maintained by its motor expressions in his attitude, it is diminished. Patients report spontaneously that these blindfolded relaxation exercises greatly improve their sleeping power. They tend to sleep excessively. Arrears of sleep are made up and pains often disappear under the improved mental condition which now ensues.

After general relaxation has been practised, attention is specially directed to one region, say the right lower limb. Relaxation of the ankle, knee, and hip
muscles is then insisted upon. First each is separately considered, then reconsidered, and finally all are linked together so that as great a degree of muscular relaxation as possible is obtained in the chosen limb.

**Movements.**—Next movements are begun. Passive flexion and extension of the ankle is first practised. The foot is placed in extreme flexion, and the patient is instructed to count slowly while the physician at a uniform rate moves the foot to a position of complete extension, pauses, and then returns the foot to complete flexion. The purpose of the passive movements is to teach the correct direction and extent of each movement. Next the patient lightly but steadily resists the passive movement. Then the movement is practised with the patient performing and the physician aiding and guiding. The physician’s aid gradually lessens as improvement occurs. And then the movement is executed by the patient alone. Finally, the movement is made against resistance. It is essential that the movement should always be completed by the return of the limb to the position from which the movement started. During every movement the patient counts rhythmically. The purpose of the counting is to educate the patient to move easily and uniformly, at a regular tempo. After the ankle, first the knee and then the hip of the same limb are educated. Besides flexion and extension, all the simple movements which can take place at the joint are practised. All exercises are done without shoes; artificial aids should not be employed during the exercises. In every case, first relaxation, next passive, then passive resisted, then passive combined with active, then active unaided, and finally active resisted movements are practised. When the ankle movements have been acquired then movement exercises are begun with knee movements; when knee movements have also been acquired then ankle and knee movements are repeated before each attempt at the hip movements; and so forth. The repetition, after relaxation exercises, of a movement which can be proficiently performed is a great aid in the learning of the next new movement.

The limb movements which are practised in the recumbent posture may also, if possible, be practised, as occasion permits, in the sitting posture. From the right lower limb we proceed to the left, relaxation, passive, resisted passive, combined passive and active, active and active resisted movements at each joint are practised as before.

Before any attempt is made to teach progression the trunk muscles must first be coordinated by relaxation and movement. This is usually easy for, the upper limbs being seldom atactic, may be used to practise lateral and forward thrusts, elevation to the sitting and resumption of the recumbent posture, with aid and against resistance.

The head and neck muscles are similarly treated. Their treatment is just as important as that of any other part. The position of the head largely governs the attitude of the body.

Too great stress cannot be laid on this preliminary training in attitude. What may be called static coordination is a vital essential to correct progression. We know from the experiments of Vierordt and others that all local movements are but maximum expressions of a general muscular change. The general muscular change must not be neglected in favor of the local movement. Coordinate movement of the lower limbs can produce only a travesty of walking if the trunk and head, are wobbly. The whole body must be taught to move harmoniously. The first essential of stability in walking is stability at rest.

After the exercises in the recumbent and sitting postures have been completed the first attempt at progression is made. Kneecaps similar to those used by carpenters, but well padded, are tied on the knees and the patient is instructed in creeping. The change from the recumbent to the creeping posture does not unduly strain the patient’s confidence in his powers of unaided blindfold progression. The creeping movements are conducted with the back as horizontal as possible; squatting must not be permitted. The tempo of the movement is again carefully regulated by counting. The direction is insured by means of a strip of carpet or linoleum upon which the creeping is performed.

After creeping has been practised for some time, first, changing from the creeping posture to kneeling up, and then, rising from the sitting posture to the upright are attempted.

In the erect kneeling posture progression is practised. Progression in the creeping and erect kneeling postures trains a person to move his body automatically with his lower limbs. This training is invaluable as an aid to walking. The dire dilemmas, which to move first, the body or the leg, how much to move the one without the other, are obviated, and the transition from standing to walking occurs almost imperceptibly.

Finally walking is taught. To maintain direction during blindfold walking, strips of carpet or linoleum are again used. These strips should be arranged parallel with the walls of the room so that the patient may at first “feel” his way. As proficiency increases the patient passes from a forty inch width of carpet or linoleum to thirty, twenty, fifteen, and even ten and five inch widths. I have at present one patient formerly very atactic who can place the heel of one foot in front of the toe of the other and thus advance on a five inch strip for a distance of about twelve feet.

These outlines roughly comprise the system of motor reeducation which I teach tabetics.

Relaxation should be as zealously practised as are movements. The patient should be exhorted not only to relax daily at definite intervals for definite periods, but also to avail himself of every opportunity to relax. When during the exercises, performance is unsatisfactory, the indication is relaxation. After a few minutes relaxing, improvement will be again evident. Every movement must be performed without strain. The moment effort becomes manifest, movement must cease and relaxation begin. To push exercises till the pulse rate rises over 110, or, as I recently saw advocated over 140, is to waste time and to incur risk. When tachycardia affects an atactic patient he cannot properly attend to movement. In the beginning, the education of the muscular sense impressions must come mainly through relaxation exercises reinforced by blindfolding and passive movement.
Vision is useful only as an aid to the spacial qualities of movements. These qualities we attain, in spite of blindfolding, by passive movements and directing strips of carpet. The harmony with which ataxies, taught in this way, learn to move, amply justifies the trouble taken with counting and passive movements. As progress is made the movements are gradually quickened, and coincidentally the passive guidance is terminated.

I have worked with some patients for two hours at a single sitting, but this is seldom advisable in the interests either of the patient or of the physician. Usually I devote from three quarters to one hour on each patient every second day. Less often than twice weekly is not enough. An ataxic thinks as much of his complaint as does any patient with an acute malady. The oftener he is seen the more satisfied he is and the quicker he progresses. I do not outline his treatment beforehand to him. Each day he receives only the task for that day. He must not be permitted to anticipate the treatment to attempt too early movements which are difficult. He must be made to follow the régime accurately and methodically.

The duration of the treatment naturally depends greatly on the physician and on the patient. My most rapid success was in a patient who had a very slowly advancing ataxia for several years. This patient, sent to me by Doctor Sorapure, of New York city, had difficulty in negotiating stairs, walked on a broad base, kept his gaze fixed on the ground, used a stick for support at every step, and had a typical but not marked ataxic gait. In less than a month he walked well, without a stick, in public. Another patient, sent to me by Dr. Vincent Williams, of College Point, New York, with whom I demonstrated at the Post Graduate Medical School, became practically preataxic in less than four months. He came under my care in November, 1912. I last treated him in March, 1913. During that time I saw him once weekly. He now (October, 1913) walks almost perfectly, uses no aid, carries no stick, conducts a large business successfully, although it necessitates much traveling, and mixes freely with his customers and others without exciting comment. He tells me, however, that when he meets anyone of special importance to him for the first time, he still feels embarrassed and has to brace himself up. This patient when he first came under my care was totally incapacitated and entered my office supported on either side by sticks held by an attendant.

Two cases which for years had been treated by the Frenkel method without much success I have been able to improve almost to the same extent. One of these, sent to me by Dr. J. J. Walsh, of New York City, I demonstrated at the Post Graduate Medical School. In them, however, I have not so far been able to produce sufficient confidence to induce the patients permanently to discard their sticks.

About twenty other cases of locomotor ataxia have been treated to a greater or less extent by this method. All have shown a degree of improvement greater than that which I used to obtain when I employed the Frenkel method. The improvement has not only been greater, but it has also been more rapidly reached. I shall later publish these cases in detail. At present I mention them merely to show that the method has already demonstrated its advantages.

The degree and rapidity of improvement is not a personal result. In the hands of two other physicians, who learned and applied the method, its efficacy has been equally proved. No failures have been reported. Both had had experience with the Frenkel method; one, indeed, had practised the Frenkel method since it was first published. Both have informed me that their success, so far, by my method has been greater and more rapid than with the Frenkel method.

I have had no relapses. Those patients whom I have discharged now tell me they have never felt better, that they have continued to improve, that now they understand their trouble, they are not alarmed by it, and if they feel any unsteadiness they have only to relax and exercise, and it disappears.

It is reported that Sir Henry Thompson acquired his wonderful facility with the lithotrite by practising, while in his carriage, the extraction of peas from his sleeve by the instrument. I exhorted my patients to relax in street cars, in trains, and under every circumstance where it is possible. They must seek coordination as the upright seek virtue. They keep a tally of the time they spend each day in relaxation and in exercise, and those who do not cooperate as earnestly as they ought and can, are disciplined.

My final instructions to them are, to practise their exercises every night and morning, to relax at all possible intervals during the day, and to avoid using a stick.

Treatment of Fear.—One point still remains to be considered—the treatment of fear. The modified shoes and the slight bandaging have a very important tranquilizing effect. The blindfolding, the relaxation exercises, the careful graduation of the movements, all encourage. The removal of the ataxia is itself a treatment of fear. The correction of attitude also mitigates fear. An erect man cannot easily be terror stricken. For the immediate combating of fear it is valuable to explain to the patient the origin of his fears, to teach him to analyze a fear as soon as it arises, and to subdue it. Deep breathing is his best weapon for this purpose.

So long as he breathes deeply he cannot become much afraid. The James Lange theory that the fear is caused by the visceral changes and not the visceral changes—quickened heart and respiration rate, etc.—by the fear, may not be wholly true, but if a person breathes deeply and thus keeps his heart's action from becoming unduly fast he cannot develop any great degree of terror.

Since I devised this method I have been surprised to find how little is essentially novel in it. The value of coordinated movements in the cure of ataxia I learned from Frenkel; the other parts I devised myself. The blindfolding which, at first, I thought I alone had conceived, I found later had been practised as far back as 1881, when Mortimer Granville in the Practitioner taught, that a patient with ataxia should be treated with preliminary excitations by mustard or cold water, and then made
to stand in a bath with his eyes closed; he furnished a rail, but the patient was instructed not to use it unless in imminent danger of falling.

Doctor Wachsmann, director of the Montefiore Home, New York, to whom I was expatiating upon the value of this method which I had then been practising for about a year, surprised me by stating, he also from the same premises had concluded that the blindfold was the more logical method; he had used it then for three months, and had had most gratifying results from it. I had the pleasure of demonstrating two of his excellent results at the International Extension Course in Nervous and Mental Diseases, held here in September, 1912.

The value of mechanical aids has long been established. Schwab and Allison in an excellent study of the tabetic foot had, unknown to me, anticipated and improved upon some of my efforts to increase the stability of the shoe. Relaxation exercises had been taught by many, particularly by those who practised here what was commonly but erroneously termed the Delarte treatment; and a faith healer had cured ataxia by allaying fear.

CONCLUSIONS.

This method avoids fatigue, promotes confidence, relieves fear and teaches coordinate movement expeditiously. It thus diminishes the coefficient of ataxia in our guiding formula (see page 1045) both by decreasing the value of the numerator and by increasing that of the denominator. Hence, the coefficient rapidly reaches unity, and coordination appears.

Coordination may not invariably be attained by ataxics through this method. The tabetic structural changes may be more extensive than the psychic mechanism can compensate, and the psychic processes may be so disintegrated by concomitant cerebral disease, that the educational and other psychotherapeutic influences which the method exerts, can avail little.

Apart from such exceptional cases, effective coordination can quickly be reestablished by the procedures I have outlined in this paper. I believe this effective coordination is less rapidly, less completely, less easily, and less permanently attained by Frenkel's method than by mine. My experience certainly substantiates this belief. When sufficient data have been accumulated from the experiences of others, a thorough comparison of the results of the two methods will be published.

40 East Sixty-second Street.

THE DIAGNOSIS OF ARTERIOSCLEROSIS.

BY LOUIS FAUGERES BISHOP, A. M., M. D.,
New York,
Clinical Professor of Heart and Circulatory Diseases, Fordham University School of Medicine; Physician to the Lincoln Hospital, etc.

Diagnosis is a peculiar and complex operation. It must include a certain measure of prognosis, a certain expression of opinion as to the existing structural conditions, a review of disordered physiology, and, in the end, one is expected to name some one of a list of disease terms as appropriate to be applied to the person under observation. So there has grown up a long series of names that are used to express results of diagnosis. This list is part of the mental furniture of each individual, whether physician or layman.

The layman often does not get further than stomach trouble, or heart trouble, or rheumatism, with a big “R,” though some of them have recently appropriated blood pressure, hardening of the arteries, and even arteriosclerosis.

The terms that physicians carry in their minds have a great deal of individuality. We have all heard of the doctor of ancient times, who told every one who came to him, not having some very definite disease, that he was suffering from a “slight diathesis,” and history records that this man's clients were perfectly satisfied.

In the diagnosis of arteriosclerosis there is this fundamental difficulty—that the disease has never been satisfactorily defined.

Only lately, Dr. Eugene Lyman Fisk sent me a great deal of literature concerning the work of the conservation of health, because I had expressed my interest in the work undertaken by a life insurance company. With his permission, I quote from American Life Waste, in which appears a chart showing that the death rate in 10,000 of population from degenerative diseases has increased in Massachusetts 67.3 per cent. since 1880, and in registration States 103.7 per cent. I would add that correspondence with Dr. Brandreth Symonds confirms the fact of the continued increase in this class of deaths.

This chart shows a truly remarkable increase in the mortality from degenerative diseases—i.e., affections of the heart, bloodvessels, and kidneys, “dropsy,” etc.—since 1880. No matter where statistics relating to these diseases are sought, the same decided upward trend is found. The figures for all the degenerative affections have been combined in the above chart, in order that any possible misinterpretation due to the more exact reporting of some particular form of disease, should be avoided. It must be apparent that, while improved diagnosis or greater accuracy in reporting, might be responsible for a marked increase in heart disease, or kidney disease, nevertheless, even in the state of knowledge that obtained thirty years ago, a death from any one of these degenerative affections would have been reported under one of the subdivisions covered by the chart. In other words, while changes in the manner of reporting might alter the mortality figures within this group, the total mortality rate, as shown in the chart, could not be affected by such influences.

Furthermore, these statistical results simply confirm a belief that has been growing among the most experienced physicians, who have observed an increasing number of such cases in their private and hospital practice.

Even if no increase could be shown, surely we should be justified in regarding a failure to reduce the mortality from these maladies as a reappraisal of our civilization.

I am disposed to include a large number of these deaths under the general term, arteriosclerosis, giving this name to the degenerative disease of the body in which the heart and bloodvessels take the most prominent part, but which is not essentially and primarily a disease of the arteries alone. This is the more so, since those competent to form an opinion on the subject have been driven to it. Many have expressed the belief that there is no worse named disease in the world than arteriosclerosis of this type.

A very little study convinces one that there is an entirely separate disease, that is essentially a disease of the bloodvessels, that should be named arteritis.
JOPSON: MEDICAL TREATMENT OF SURGICAL CASES.

By John H. Jopson, M.D.
Philadelphia.

The attempt to bring within the scope of a paper such as this, a consideration of even the outlines of the subject assigned to us, would seem to be a well nigh impossible task.

When one remembers the many forms of medical treatment, including pharmacotherapy, dietotherapy, sorootherapy and bacterintherapy, hydrotherapy and mechanotherapy, psychotherapy, and others in constant use, and most of them applicable at one stage or another in a large proportion of surgical cases, their mere enumeration will suffice to indicate the vastness of the subject. It is selfevident that any one of these methods alone could furnish the subject for a prolonged discussion which would indicate only the outlines of the field and not fill in one little corner with the technical details. If, for example, we should confine our attention to a consideration of medical treatment in its narrowest sense, namely the use of drugs as an adjuvant to surgical measures, we could scarcely indicate the general principles of therapeutics as applied in surgery, whether before, during, or after operation in the uncomplicated case, to say nothing of the intelligent discussion of the many medical problems which may arise during the progress from sickness to health of the individual who suffers from a surgical ailment.

It is apparent that the subject must be studied from a different standpoint than the enumeration of lists of drugs with their indications. Again, it is not our intention to discuss the error into which medical men sometimes fall, by persisting in the medical treatment of cases which properly belong to the domain of surgery or habitually adopting internal treatment as an alternative to the knife. Such medical treatment of surgical cases, while common enough even at the present time, is fortunately becoming less and less frequent, and there are indications that, in the judgment of some profound thinkers, and we would include some surgeons in this category, the pendulum has already swung too far in the direction of surgical intervention in certain fields, and that we are being urged or encouraged to undertake operations for certain disorders, the causes of which are found in morbid chemical processes of nervous origin, rather than in mechanical or other localized pathological processes.

It is rather to a résümé of some of the well recognized principles which guide us in the internal treatment of surgical cases, that we would call your attention. These include a recognition of the necessity for, and of the relative importance of those measures which can be grouped under the head of medical treatment in various types of surgical cases, and their relation to preexisting medical conditions. Also the modifications of medical treatment which are called forth by surgical complications arising in connection with such preexisting disease and the desirability of special training in the handling of them; the necessity of organizing our hospital work so that the medical treatment of surgical cases may be amply provided for; and finally, the wish that something may be offered for discussion which will stimulate us in our efforts to improve our methods of treatment, for that such improvement is possible or needed, the initiation of this discussion would seem to indicate.

There are certain broad and universal indications for medical treatment in all surgical cases which
it may be as well to define at the outset. We may take, for example, such treatment as is indicated in what may be somewhat incongruously termed the "normal" surgical patient. By this we mean the individual who comes for an operation, it may be for a benign tumor or for a malignant growth in its early stage, or for an intercurrent operation for some chronic condition which has not as yet seriously affected the general health; an individual whose metabolism is normal and whose functions in general are not seriously embarrassed. In such cases the problem is the performance of a major operation for a local condition which is uncomplicated by other morbid states and in which medical treatment, barring complications which develop as the result of the operation, may be reduced to a minimum.

Medical treatment would then include the preliminary preparation in the way of diet and attention to the gastrointestinal tract, which is usually considered necessary to the administration of a general anesthetic, and the performance of a major operation, modified in some degree by the region which is to be invaded. If, for example, an operation on the upper abdomen, the gallbladder or the stomach, is contemplated, the preparation may differ somewhat from that for an appendectomy, and this again, from that required for an extra-abdominal operation.

At the time of operation certain medical measures may be demanded, usually of an emergency nature, to combat by internal means such complications as shock and hemorrhage. Following operation, pharmacotherapy, to allay postanesthetic discomfort and vomiting, to secure sleep, to relieve pain, to insure proper action of the bowels, to conserve kidney function, is often indicated, while a continuation of treatment for such complications as occasionally arise as a result of the operation per se, if such exist, will of course be demanded. The general care and oversight of the patient will cease only when he or she is restored to complete health, and the responsibility of the surgeon is usually considered to terminate, only when such a stage has been arrived at. Such are the indications, briefly enumerated, in the "normal" surgical case.

We can easily define several other classes of cases almost equally numerous in which the indications for medical treatment are more acute as well as much more numerous. These would include the large groups of surgical emergencies in which a severe or dangerous condition develops before the patient reaches the hands of the surgeon, either as the result of trauma, or of the nature of such surgical disorders as fulminating appendicitis, the internal or external strangulation of the bowel or one of the many surgical accidents which admit of scanty preliminary preparation and treatment. In such cases intervention must be undertaken not regardless of, but in spite of the general condition and complicating ailments. Shock, hemorrhage, and sepsis will be more frequently encountered than in the first group we have considered. Medical treatment of an energetic nature, usually in such forms as the surgeon is most familiar with, is constantly demanded, and often in the guise of methods of treatment which have developed in the hands of the surgeon himself in response to the frequent demands which he encounters in his daily work.

There remain other classes of cases in which the indications for medical treatment are equally urgent and more complicated. For example, a surgical emergency frequently arises in the course of a serious acute medical illness for which the patient is under treatment or as a direct sequel of the same, as for example, the perforation of an intestinal ulcer in the course of typhoid fever, a gangrenous cholecystitis developing under the same circumstances, or an empyema which follows closely on the heels of a croupous pneumonia. We have added to the original pathological process for which the patient is under treatment, a complication which, while it may for the time overshadow in importance the original ailment, and call for the institution of a new train of remedial agents which are adjuvants to surgical intervention, and are necessitated by the new indications arising as a result of the surgical complication, cannot displace entirely those therapeutic measures which were demanded for the illness from which the patient still suffers or from which he has only just been relieved. In such cases, medical treatment in all its forms assumes an importance which transcends that present in the groups we have already considered, and by reason of which the therapeutic resources of surgeon and internist alike may be tested to the utmost.

Again there is an equally important group in which some preexisting chronic morbid process exists in combination with an acute or chronic surgical condition, and in which said surgical condition may be independent of or directly dependent upon it, but in which the medical and surgical treatment alike are modified by its presence. Among such complicating medical ailments, it is necessary only to mention arteriosclerosis, nephritis, diabetes, chronic alcoholism, and senility as a few of the morbid processes constantly seen in alliance with surgical disorders, and all of them of prime importance in modifying the prognosis and treatment of a host of surgical conditions. Again in such cases medical treatment of a highly specialized nature may be necessary to insure a favorable result.

Finally, there is a limited group in which there is still, it may be, a fair opportunity for division of opinion as to which class, medical or surgical, the case belongs: in which the battle for possession between the internist and the surgeon still continues, or in which medical treatment must be continued until a favorable moment for surgical intervention is reached. A case of exophthalmic goitre at the top of a wave of hyperthyroidism may be fairly considered under this heading, one in which surgical treatment has not yet had a trial, or in which the preliminary ligation of the thyroid arteries is to be followed at a favorable moment by a lobectomy, and in which medical measures are of manifest value; this will furnish a fair example of the nature of the cases which we group in this place.

A review of this more or less artificial classification will show that in a generous proportion of our
surgical patients, medical treatment is reduced to a minimum. In another class while the indications are acute they are mainly those which call for methods of treatment with most of which, as practised at the present time, the surgeon is thoroughly familiar, and for the evolution of which he is largely responsible. In the remainder, a combination of medical and surgical indications exists, which in the more serious cases may put to the test the resources of the most expert therapist as well as the most accomplished surgeon. In the aggregate an amount of medical knowledge, and a facility in its application is demanded which should put to shame those who would classify surgery as a mechanical pursuit. These are the demands which our surgical patients make upon us. How and by whom are they to be met?

The ideal surgical attitude is not that which contents itself with the extirpation of this or that diseased focus or the correction of this or that abnormal condition, but which considers the organism as a whole and either consciously or unconsciously endeavors to restore its equilibrium. As Musser has said: "The organism which is in perfect equilibrium with its environment and has all its parts in equilibrium, is in a state of health." It should be the object of the surgeon to avoid, as Musser emphasized, "the old idea that disease is a special 'something' within the organism, the casting out or the removal of which is brought about by a special method adapted to each case." Hence, it must be that if the responsibility for restoration to health after an operation be with the surgeon alone, to him will fall the direction of many forms of medical treatment; that is to say, if he is not to remain content with removal or correction of the cause on the one hand, or the effect on the other, without regard to the condition which, as Musser said, is the disease. The dashing surgeon in Bernard Shaw's witty and abusive travesty on the medical profession, who corrected all ills by the removal of the "nurkrin sac," was probably frequently at fault in his diagnosis. But granting that his diagnostic ability was unerring, he would still be greatly in error if his treatment stopped at the removal of the offending cause, without making provision for the after care of the case. This after care would include those therapeutic aids to restoration of the normal functions of the various secondarily affected organs and the various physical and psychical disorders which had been produced by their faulty activities.

As a consequence of this responsibility for the end result, which rests upon the shoulders of the surgeon, we find that in the great majority of instances, the medical treatment of the surgical case is left largely in his hands, except in certain of those borderline cases already mentioned.

In the main, it may be said that the medical measures employed by the surgeon are not radically different in the majority of instances from those of the internist, except in so far as they are modified by the training and viewpoint of the surgeon as influenced by the conditions which he most frequently sees.

Most of his therapeutics as applied to surgical conditions, he has learned after leaving the medical school. As Wilbur has said, in discussing the teaching of therapeutics, "The historical element, which is such a strong factor in hampering our medical schools, still separates medicine and surgery from therapeutics. They must all go together and grow together."

In considering the treatment of the "normal" surgical case, so called, it is to be remembered that complications are few and the after treatment has been of late much simplified. We no longer consider it necessary that our patient should be tortured with thirst, refused a harmless anodyne, vigorously purged on the second day, or starved until the fourth or fifth day. As little interference as possible with the patient's comfort, and with the normal functions, is the standard of most operators. When indications for medical treatment arise in such cases, they are generally clearly cut, and the therapeutic measures employed and the drugs prescribed are comparatively few in number and those which as a rule give the promptest result with the minimum of dose. The surgeon usually aims to administer quick, decisive blows when he has to drug his patients, for postoperative conditions forbid the more slowly acting and stomach disturbing remedies which the medical man might be tempted to order. As we have already said, the surgical therapist must receive special training in prescribing. No more forcible example is needed to illustrate this fact than the experience all surgeons have in our hospital wards when a resident physician goes on duty on the surgical side, after serving his time on the medical service, especially if he be a therapeutic enthusiast whose activities have previously had full sway. We constantly find it necessary at such, unfortunately too frequent, intervals to visir the treatment sheets of our surgical patients, and to eliminate a long list of drugs, slow of action, inefficient, or overstimulating, and disturbing to the gastrointestinal tract, and to substitute those simpler remedies which have proved their worth in surgical practice. To a patient suffering from pain and sleeplessness after operation a hypodermic of morphine is worth many doses by the mouth of bromides, trienal, sulphonal, veronal, or other forms of slowly acting hypnotics. Hypodermic stimulation for the flagging circulation, carefully watched, and such swiftly acting agents as camphorated oil and ephedrin displace the more slowly acting remedies which are habitually administered in many medical emergencies, while enterolysis, hypodermolysis, intravenous infusion, and transfusion, measures which the physician has quickly appropriated for his own, are in more or less constant use.

Nor is the surgeon a stranger to those preparatory methods of treatment which a careful study of his cases will often determine to be necessary. Indeed, upon the institution of proper medical treatment in the line of preparation depends much of the success of his operation and the freedom from complications thereafter. Careful physical examination and investigation by the most modern laboratory methods of each and every organ and system, cardiovascular, respiratory, gastrointestinal, genitourinary, and nervous, are indicated in all cases which admit of the time for such preliminary study.
The indications for medical treatment which such a preliminary study furnishes, may call for the transference of the case, for a time, to the internist before operation is undertaken, but in many cases the surgeon will be his own therapist in directing the preparatory treatment.

Still another line of preparatory treatment has been added to our armamentarium, and that in the form of the anoci association methods of Crile. Anoci association embraces both psychical and physical measures, many of them long employed by men of tact and judgment; others, comparatively few or entirely novel, but all put upon a systematic plane and a logical physiological and therapeutic basis by this enthusiastic and gifted surgeon.

The principles of anoci association are undoubtedly of great value, especially in those borderline cases where, as Crile has phrased it, the threshold of the brain is lowered to the entrance or effect of anoci associations. In the carrying out of the anoci association methods, medical treatment may be said to be represented in various ways, especially in the line of psychotherapy, and for their proper use not only is a well trained hospital staff of prime necessity, but the demands upon the surgeon's time in connection with them are not inconsiderable.

The question which we are attempting to solve in this discussion is: Are we giving our surgical patients the medical treatment which they should receive; or, has the time arrived for review, rearrangement, and reform?

Most surgical work is done in hospitals, where it should be done, and in these days when hospital reorganization and reform are in the air, the interests of the patient should receive the first consideration. It is unfortunate that in so large a majority of surgical cases the connection of the internist with the case ends when the diagnosis has been arrived at, and the patient transferred to the surgical ward. The internist may and should follow the patient to the operating room to see his conclusions confirmed or proved erroneous, that he may obtain the chance to glorify, or excuse himself, as the case may be, as well as to learn these lessons of living pathology of which we now hear so frequently. When the patient goes back to the ward after operation the responsibility of the physician is usually considered as ended, unless he be called upon to combat some complication of a medical nature with which the surgeon feels unable or unwilling to cope. If the patient is a private one, the medical man often follows, through necessity or desire, the postoperative course of the case and is then in a position to offer his services as a skilled therapeutist. But the great majority of our cases are of ward patients, and in losing touch with them, the medical man does not have those opportunities to familiarize himself with postoperative conditions and with special therapeutic indications which he might otherwise enjoy.

For the diagnosis of surgical conditions we must humbly pay our tribute to the many contributions on diagnosis which we owe to the medical man. It was Fitz, who by his studies, placed the pathology, symptomatology, diagnosis, and indications for treatment of appendicitis upon a scientific basis, and it was Wilson who first suggested operation in typhoid perforation. If we examine more closely into the history of the improvements in preoperative and postoperative treatment, it will be apparent that we owe them mainly to the surgeon. The notable contributions to the treatment of peritonitis, the aftermath of appendicitis, have come from such men as Murphy, Deaver, and Fowler, who, constantly associated with this and similar complications, were able to detect the necessity for something more than purely operative treatment, which would aid the peritoneum and the organism in general in limiting or overcoming such widespread inflammatory lesions. We mention this particular example as showing the evidence afforded the trained mind by continual observation of postoperative and complicating conditions.

We are far from the limits of useful knowledge in the treatment of this and allied surgical disorders as well as of complicating medical conditions, some of which threaten the success of an operation, while others add greatly to the patient's discomfort. Both patient and surgeon suffer from the lack of coordination with the internist after operation, which would certainly smooth the road to convalescence on the part of the patient, while it would lead to the discovery and adoption of newer methods of postoperative treatment by which the trained therapeutist would be stimulated and obtain an opportunity to develop. Both sides are the losers in this lack of cooperation following operation. It is painful, for example, to have the daily experience of seeing in consultation with men who are really expert diagnosticists, cases of appendicitis in which the physician tells us as a matter of course that the bowels have been thoroughly opened by the administration of laxatives and even more drastic purges. A few short excursions into the surgical ward would show him that he has committed a grave blunder and one which militates against the success of an operation.

In this respect the surgical intern of brief experience dwells on a safer therapeutic plane than a graduate of fifteen years' standing, who has not learned the lesson that physiological rest offers the best opportunity for localization of a virulent inflammatory process and that the bowels are not inflamed in these cases because they are inactive, but that they are inactive because they are inflamed.

At the present time the problem of medical treatment in the surgical wards has still another side to it. This is due to the fact, that the purely operative side of surgery occupies so much more of the surgeon's time than was the case but a few years ago and reduces by just so much the time which he spends in the wards and devotes to the medical side of his cases. When we consider that our busiest men spend from three to six hours daily for several days a week in the operating room, and this in addition to the time devoted to office practice, to consultations, to teaching, to study, and to the preparation and the discussion of papers on surgical topics, it seems like attempting the impossible for them to continue with the entire responsibility of all cases under their care, no matter what the complications may be. This tax upon their time has resulted in the past in the adoption by many surgeons of a so
called postoperative schedule as some protection against the vagaries of a partially trained assistant. The value of such inelastic schedules is open to serious doubt. They give too little consideration to the individual and the aberrant case. Nothing can replace the careful daily bed to bed inspection by the surgeon or by a properly qualified assistant, and in the organization of surgical services to-day, the necessity for such assistance is generally recognized.

To attempt to more than hint at the necessity of thorough organization of our surgical services and the provision for something more than the oversight afforded by resident physicians is out of place at this time.

The day when one surgeon with an organization which comprised nothing more than the assistance afforded by house physicians would care for a large and active service is now out of date, and it is becoming generally recognized that we must have provision for one or more assistants in the wards whose duties are sharply defined, whose authority is recognized on all sides, and whose oversight of both medical and surgical treatment insures a maximum of efficiency on the part of both visiting and house staffs. We would not wish to be understood as saying, that in the past, all of our busy operators have not given to their patients with the assistance of their house staffs, the medical care they should. There are Admirable Crichtons in our profession too, and the devotion with which their patients repay them in after years proves that the most interested party can vouch for the completeness of the attention which he has received. But we are dealing in this discussion, not with individuals, but with general principles, and it would be a blind conservatism which failed to see some opportunities for improvement. There will always be some surgeons who excel in diagnosis; others in operative skill; and still others in medical treatment and the aftercare of their patients. Even the laity are quick to realize this, as we have frequent opportunities to learn. Homer Gage in a recent article on Some Abuses in Surgical Practice, brings out the point, that in his opinion, "the purely mechanical side of surgery has been receiving far too large a share of our attention." This view has been forced upon him by a knowledge of the indiscriminate and reckless operations performed to-day by extremely radical or by partially trained men. His remarks cannot be interpreted as meaning that the surgeon can be too familiar with the most improved methods of technic or too dexterous in their execution, if such knowledge and dexterity decrease the risk of operation or insure the most favorable result. They can only mean that such knowledge and training should not be obtained at the cost of a knowledge of pathology, of diagnosis, or of time devoted to careful and thorough preliminary examination of the patient, or to medical oversight before and after operation. Nor can manual dexterity take the place of that good surgical judgment upon which Finney has written so forcibly and eloquently, and a congenital absence of which, or the failure to acquire by hard work and long training, separates the safe from the unsafe man.

Lawson Tait at a meeting of the British Medical Association in Birmingham advised those present, including surgeons, not to waste their time on the scientific exhibits, but to visit some of the great industrial establishments and learn to imitate the manual skill of the Birmingham button makers. Such a remark probably did not add to his popularity with the committee on exhibits, and revealed a point of view not entirely in harmony with our own at the present day.

**CONCLUSIONS.**

We have tried to demonstrate in this review of the subject:

1. That in practically all surgical cases there are certain fixed indications for medical treatment, less in some and greater in others, and that while such indications can be reduced in number, they cannot be done away with entirely. In some instances they are acute, and in others complicated and demanding great therapeutic knowledge and skill to successfully cope with them; moreover, that their proper treatment is modified to some extent by the surgical conditions present, and by operative as well as non-operative surgical methods of treatment.

2. That there exists a need for special training along these lines, and that there is room for improvement in our medical treatment as seen in the rank and file of our cases and in the hands of all of us.

3. That in a thorough organization of our hospital staffs which provides for cooperation of physician and surgeon in the line of treatment at all times, there are opportunities for improvement which only such association affords. Something more than a haphazard cooperation at critical times is needed to insure success in all cases, and in our plans for hospital reorganization and reform some provision must be made in this direction. If the physician on duty, with his assistants, could pay weekly or semi-weekly visits to the surgical wards in company with the surgical staff, and go over the medical treatment of cases with the surgeon, there would be afforded the opportunity for the medical man to familiarize himself with the needs of surgical patients, and for the surgeon and surgeon together to foster methods of preoperative and post-operative treatment that not only would add greatly to the comfort of the patient, but would in time greatly increase our therapeutic knowledge and open new fields of medical research. A striking illustration of the value of cooperation is seen in the new field of bacterium therapy, where the association of bacteriologist and surgeon in this highly specialized form of treatment is usually considered necessary. Time does not permit an amplification of this subject, but it need only be pointed out that few surgeons, unless with special and very recent laboratory training, care to "go it alone" in this field, and now that the days of therapeutic nihilism seem rapidly vanishing, and the search for specific forms of treatment of synthetic and biological character is being so ardenly pursued, we believe that every opportunity should be afforded for their development by those best qualified for the investigation.

1824 Pine Street.
INFECTIONS OF THE HAND.

By Irving S. Haynes, Ph. B., M. D., New York.

The importance of properly treating infections of the hand is sufficient justification for bringing this subject often to the attention of medical men. Any one who is connected with a general hospital where acute conditions predominate soon realizes the large proportion of cases presenting injuries and infections of the hand. Here we also find the bad results from timid surgery. The importance of early recognition of the seriousness of finger or hand infections and the importance of instant and adequate treatment are almost daily emphasized by the number of surgeons themselves who have to pay the penalty for slight needle pricks or knife cuts received in the course of operations. In this morning's paper, for instance (September 30th), I notice the serious, if not fatal, illness of two surgeons from such causes.

After many years' experience with such cases, I feel that the burden of my message is—**instant, intelligent, and thorough first aid treatment.**

I shall not in this brief communication attempt to cover the entire field of hand infections. To one who would seek to learn much of the entire subject, I would refer to Kanavel on Hand Infections. There the subject is presented from the anatomical, bacteriological, pathological, and surgical aspects in a thorough manner.

First the importance of the hand in one's daily life. That is readily seen, but not so often appreciated until a hand or even a finger is put out of business by some infection.

If you need an illustration of the importance of a hand in your own life, just put one hand—it will not matter which—into a sling and live twenty-four hours without it, if you can. Or if that is too severe and unnecessary a test—put a splint on one finger for the same period. To be sure, you will lack the effects of septic infection; the pain, fever, swelling, etc., but you will have demonstrated the great need of the hand in the human economy.

To deal with hand infections successfully with the preservation of the greatest functional results, one must have a very definite mental picture of the anatomy of the part. It matters little whether you can name the structures, provided you know the function of the various structures and their relative positions. In infections, the most essential anatomical structures are the various tendons and their synovial sheaths. The tendons, because if they are destroyed or left fused together, movement in the parts supplied by them ceases. The synovial sheaths, because by their presence infections are easily disseminated and their effects rendered more disastrous. The lymphatics, which in the forearm and arm play so important a rôle in the spread of infections in those localities, may be disregarded in considering the spread and treatment of hand infections.

I shall only briefly consider the anatomy of the region. The synovial sheaths of the flexor tendons of the thumb and little finger extend to the insertion of those tendons, they also reach about an inch above the annular ligament of the wrist, and in the palm of the hand the sheath for the little finger tendons widens out to embrace all the other flexor tendons and reaches to about the middle of the metacarpal bones. While these two burse are usually separate, they frequently communicate with each other, and in the presence of infection are to be considered as a single sac with thumb and little finger extensions.

The intervening fingers have separate sheaths for their tendons. These sheaths usually extend to about the heads of the metacarpal bones. There is thus an interval of about half an inch between these synovial sheaths and the large palmar sac.

Another factor in determining the seriousness of hand infections, is the almost impermeable dense fascial covering formed for the tendons and their sheaths by the annular ligament, palmar fascia, and the fibrous sheaths for the various tendons. Thus put up within these osseofibrous pockets and channels will wreak irreparable damage to the tendons in a few hours, because there is no chance for adequate expansion, the blood supply is shut off and the tendons die. This also explains the early and pronounced systemic effects from such infections.

Pathology explains what microbial action does to the wonderfully smooth surfaces of tendons and sheaths. How the epithelium is destroyed, and how raw surfaces are left to grow together to greater or less extent. A little longer, and the tendon is destroyed and it is cast off as a dead mass and the motive force is no longer able to act upon the fingers. But this is not all, though bad enough. There is the destruction of other structures, fascial sheaths, muscles, bone and partial loss of the hand or the entire member, for such infection is not confined to the immediate locality where it began its action, but speedily, through the action of the lymphatics, is carried to distant sources, so that not only is the hand in danger of being lost, but also the whole extremity and even the patient himself may succumb to the infection.

Consider also the results which follow infections you have seen. Nothing may show but a small scar—no loss of function, or you may have seen all gradations from one finger stiffened by such an infection to not only its loss, but of varying degrees of damage to the other fingers, the hand, and the entire upper extremity.

With these oft repeated pictures fresh in your mind, what will you do when the next case of infection comes to you for treatment? That is the question. Will you "prick" the infected centre with a quarter inch cut? Here is where the trouble arises. Here is when the responsibility is laid upon the medical man. If you know what to do, do it. If you know what to do, but for one reason or another cannot carry out the right treatment, or if, frankly, you do not know just what should be done, in either case send the patient where he can get the proper treatment at once. Delay may mean function lost forever.

What to do? The principles of treatment hark back to the anatomy of the hand and the pathology of its infections. Infection, by whatever means, in either thumb or little finger, may rapidly extend to the respective flexor sheath; if this occurs, it will not be long before the palmar extension of that
tendon becomes involved, then the other palmar sac and so on to the digital extension of that sac. Thus in the case of a woman who cut her thumb on a kitchen pan. The infection extended to the flexor sheath of the thumb, to the palmar bursa, and into the little finger extension, so that I found pus not only on incising the flexor sheath of the thumb, but also on incising along the ulnar border of the palm, and irrigating fluid freely passed from one incision to the other. It may extend further beneath the annular ligament to the sac about the tendons above the ligament. Pus here is in a dangerous locality. It may easily break through the thin synovial barrier and spread uninterruptedly to the forearm.

When infection is received in the three middle fingers, it is usually limited in its spread to the finger attacked, but may extend into the palmar bursa by involvement of the intervening loose tissues along the tendons. There is no guarantee that because the infection is received in one of the three central fingers, that the palmar bursa will not be involved, just as it is almost certain that infection in the thumb or little finger will eventually involve that same bursa.

I shall not dwell upon the treatment of these conditions in their terminal stage; by that time the case is usually referred to one who has experience in these cases. I shall consider the case as usually presenting to the family doctor. The principle of treatment is just the same here as with infection anywhere else, and that is, free drainage. The difficulty lies in the multiplicity of structures which may be involved and in the lack of knowledge on the part of the doctor, just where those very important structures are. Free incision must then be made with reference to the important structures beneath the skin. The family doctor is then between the deep sea of an imperfect knowledge of the anatomy of the part and the devil of a pus pocket which he knows he must reach. He compromises with his lack of anatomical knowledge and the necessities of the case by sticking a narrow knife into the infected area, and is content with an incision a quarter of an inch long, which is promptly closed by the plug of fat forced into the little skin incision by the pressure behind. Some blood and a few drops of pus may escape. A dry dressing of iodoform gauze is usually put on the part and the patient sent home, laboring under the delusion that something has been done. Twelve or twenty-four hours later, the delusion in both minds is dissipated and both realize that "something more must be done." This may be more stabs or it may be a radical operation. I advise the latter.

What should be done? The location and extent of the infection decides. Local anesthesia may be sufficient, general anesthesia may be necessary. Take the usual finger infections. They are most often in the pulp of the finger, the clinical symptoms need not detain us, they are too well known. Cocaine or novocaine is going to be used or some other local anesthetic, for some anesthetic is necessary. The work is done aseptically; that goes without saying. Place a rubber band or a soft rubber catheter about the base of the finger, tight enough to constrict the venous return, inject the digital nerves beyond the ligature, two on each side, through single needle punctures, allow a few minutes to elapse and the entire finger becomes dead to pain. Now open the infected area to the bone, even if such incision opens the tendon sheath. Swellings upon the back of the finger, unless here is the site of infection, need not be opened. The swelling here is edema and will disappear once the primary focus is drained. In cases where there is extensive infection, I do not hesitate to open the tendon sheath for its entire length in the finger. It is neither necessary nor desirable to try to save the annular ligaments in the event of such extensive infection, because it is at the site of these firm bands that tendon destruction will be caused by pressure, which shuts off the blood supply to the tendons. If this can be prevented and the tendon preserved, the annular bands will subsequently be reformed and some function be regained. Free drainage is the imperative end. It may be necessary to add to the incision opening up the tendon sheath, one or two others along the side of the finger. These incisions will close quickly when their purpose has been served. Drain by rubber tissue. Do not use gauze; it stops up the opening and is painful to remove. Rubber tissue holds apart the cut surfaces—and that is all any drain will do—it may be removed and reinserted subsequently with little pain. Let the parts bleed freely. Put in no sutures. If a digital artery is cut, pick it up with a small clamp and ligate it. The foregoing holds good for all of the fingers.

As to primary palmar infections. Put the elastic ligature about the wrist to hinder the venous flow and to confine the anesthetic. Infiltrate the skin over a long area. Make the incisions first only through the skin and in the direction of the fibers of the palmar fascia. Any incision less than an inch long is futile; it may need to be twice this. This incision divides only the skin and fatty pad down to the palmar fascia. Your anatomy tells you that there is nothing to be careful of, superficial to this fascia. It may be that the infection is all superficial to the fascia; if so, the work ends here. Usually the infection is deeper; it must be reached. At once visions of the palmar arch, digital vessels and nerves and the tendons come to mind. Possibly you may cut the arch. What harm? The ends of the artery can be seen spurting, and can be caught and tied. No one need get nervous and stop short of doing his duty by that fear. To be on the safe side, bore through the fascia with a pointed artery clamp, open it wide, and thus make an opening fully an inch in length. Insert the rubber tissue drain.

If the palm is more extensively involved than this, the entire hand will also be greatly swollen, a general anesthetic will be needed and a radical operation demanded. This means that the palmar sac must be opened along the anterior ulnar or radial border of the hand, free enough to pass one's finger into the infected sac from either or both sides. This case presupposes infection starting in either the thumb or little finger, whereas the palmar infection presupposes that the infection has been received in the palm itself.

If the palmar infection has reached into the bursa above the annular ligament, this should be opened by an incision along the anterolateral border on the ulnar side. It is seldom necessary to make
a similar one on the radial side, though it should be done if the pus pocket seems to extend that far. Another point; in this extensive condition, where the very life of the tendons is in the balance, and the pressure of the annular ligament is found to be constricting them, I have not hesitated to divide this structure freely and make an incision from above to below this structure, through this ligament, widely opening up the entire region. Not often is this necessary except in the neglected case. If the tendons are preserved with any function left, the divided annular ligament will firmly unite and not detract from such function. In these cases the back of the hand will be found tremendously swollen. Some stab incisions merely through the skin to allow of serious oozing may be necessary; usually these are not needed.

If one finds that the pus has worked back between the metacarpal bones, free posterior incision or incisions will be demanded. These cases, though, are the extreme ones. Added to the work on the hand there will probably be incisions needed to open up the forearm and arm possibly to the shoulder, but this is another story.

No matter where the site of the lesion, the dressing is the same—a wet dressing of boric acid with a large amount of gauze and the application of a splint to hold the parts immovable. As Ochsner says, rest is necessary to combat infection and prevent its spread. The dressing should be kept continually moistened with warm boric acid solution. It does not require changing oftener than once in twenty-four or forty-eight hours. I agree with Ochsner that the dressings should be changed with the minimum traumatism. If the drains are working it is not necessary to remove them and reinsert others. I use no irrigation, especially of hydrogen dioxide so commonly advocated. Pus will escape to the surface if the proper drain has been inserted at the first operation and brutal squeezing and forcible irrigating will not be necessary. These measures only damage the already weakened tissues and disseminate the infection. Passive or active motion should not be begun until all evidences of acute inflammation havesubsided. The patient's sensations are the best guide to this.

A word to a colleague who pricks his finger at an operation. This is based on my own experience covering many years. Stop work at once; your assistant can attend to the patient for a few moments. Whip off your rubber glove and use it as a Martin bandage to drive the blood from the web to the end of the finger. Force free bleeding; from three to five minutes will be sufficient. Dry and apply tincture of iodine. Put on a clean glove and finish your operation.

107 Wst Eighty-Fifth Street.

THE CRIMINAL'S PLACE IN PSYCHIATRY.

By Henry M. Friedman, M. D., LL. B., LL.M.,
New York.

Acting Assistant Surgeon, United States Public Health Service.

The subject of crime and criminals, because of its nature, would seem to be, and, indeed, has been thus far, wholly within the sphere of the jurist. But since crime and criminals are merely phases of life, the subject comes truly within the scope of the natural and medical sciences. The biogenic nature of many subjects previously not so considered has now been given definite place by scientific researches. Now, this subject of crime, of such vast importance to civilization, is gradually finding its place in the field of medicine, but particularly in the special science of psychiatry. The goal will have been reached when criminals are some day placed definitely in the class of the insane or the otherwise mentally defective; and when the criminal act will be found to be merely a symptom or manifestation of the psychic condition; and, further, when the various crimes will be found to be symptoms peculiar to definite forms of mental disorder or defect. Even the very recent term, criminally insane, while an attempt at the recognition of the mental nature of crime, is paradoxical, for how can an insane person be a criminal, or a criminal, as such, be insane? The problem has, however, been sufficiently solved to call attention to the close relationship existing between criminology and psychiatry. We can all appreciate that the step from the old treatment of the insane by flogging out the evil spirits, to the present humane conception of proper treatment, is a longer one than that which would treat all crime as a disease manifestation of the mind.

Learning the term crime, since it cannot be freed from its relation to the legal, and especially since it is in that sense that the term is most used, it should be understood as meaning an act which injures the public in its social aggregate; it is any antisocial act. Civil wrongs, or torts as they are called, injure only the individual, though a particular act may be a tort as well as a crime, since it may injure both the individual and the public. For an act to be a crime, there must be an actual or constructive intent to commit the act committed, in a mind capable of having an intent. Intent has no import in tort. If intent, actual or constructive—in the latter where an intent to commit the act committed is construed from an intent to commit another wrongful act—cannot be shown, there can be no crime. It is the propensity of the mind for the crime that governs. How difficult this is to prove is shown by the fact that this question, of so much importance, is left to the determination of a chance jury, in the hope that their numbers will more nearly determine the truth, though it would seem that the training, education, and experience in these matters of the jurist would offer a greater chance for the divination of intent.

In law, crime is divided into two classes, malum prohibitum and malum in se. The former is crime only because made so by law for the better discipline and welfare of a community, such as the health ordinances, speed regulations, etc. The same acts in another community might not be wrongful, probably because the necessity had not arisen for making them so. Real crimes—malum in se—are such acts as are wrongful in themselves, from their nature and without regard to laws. They would be wrongful even if, so to speak, the law permitted. The dictator here is not the law but the moral sense, and the failure to possess such dictation denotes moral turpitude. It is true that with advancing civilization the moral code of what is right and
what is wrong keeps just ahead of the laws enforcing the right. Even with these distinctions, and with these limitations on the nature of crime, the subject must yet be treated very broadly, and to a large degree very unsatisfactorily, since the mind must embrace a variety of conditions under a variety of social organizations, and especially because our knowledge on this subject is still very meagre. The matter has just begun to receive proper attention, and just as much of our progress in insanity as well as in anthropology lay in unlearning our errors, so that now we know less than we did previously, so will it be for a long time with this subject. Besides, the question of what is right and what is wrong can never be fixed as a definite entity, for it is as limitless as the universe itself, and will develop and change and be revised in the process of evolution.

Crime, then, is any antisocial act. It is an act which the presently constituted society recognizes as wrongful, and an unjustifiable injury to that society. Havelock Ellis says that "to be a criminal deed the crime must be exceptional in the species and must provoke a social reaction among the other members of the species." The same acts may not, however, outrage any social feelings under other conditions or among other species. "Crime consists in a failure to live up to the standard recognized in the community as binding." This failure to live up to the standard is due either to a mental inability to recognize, to appreciate, or to conform to this standard, in which case we have the out and out lunatic, or to a mental unwillingness, though there is ability, in which case we have the criminal as at present understood. In both instances it is not the act so much as the state of mind which produces the act which is in question. The mental ability to recognize the standard makes an individual responsible for his act. But aside from the speculative psychology of crime, a great deal of the crime has already been traced to the door of the insane and mentally defective. The law concedes the mental nature of all crime when it defines the malice necessary to show intent as a depraved mind which does not regard the rights of others. A depraved mind by its meaning is an inherent condition, but the law punishes the criminal for having it. It might as well punish him for having an appendix. Punishing such an individual is literally to fog out the evil spirit of depravity. On another theory, the criminal's conception or lack of conception might be normal for a lower or preceding state of society, which theory places the crime and its perpetrator at the door of atavism. Even so his atavism is an integral part of the criminal, for the possession of which he can in no wise be held responsible; in all probability it is an hereditary quality handed down to him from some near or even remote ancestor.

Political crimes and crimes of passion cannot be explained on grounds of insanity or defect, nor on atavism. In political crimes the forces against which they are directed may be the antisocial ones—as history has so often shown. In crimes of passion, and during the mental explosion accompanying it, the individual is bereft of the control inhibition over the volition; his acts are rather reflex in nature, for which the mind is not responsible. This, however, makes the act psychic or ultra-psychic in character. At all events such passion explosions do not speak for a full mental development, but rather for deficiency, since civilization aims to control reflex actions, and to put more of them under the control of the will. Education aims to teach control of natural or reflex propensities. Properly adapted education would take a great number out of the criminally inclined, especially if this tendency were discovered early. On the other hand, we find that in the assassination of prominent individuals by persons believing they have a political grievance, we are dealing usually with a lunatic whose present act is the culmination of a series of insane acts, or with persons constitutionally inferior, but previously not guilty of any insane acts. These individuals are unduly impressed by events of trivial significance, are unable to discern for themselves the true value of things, their emotions are highly magnified, and on them trivial impressions produce mental explosions culminating in the crime. But for these impressions, the result of actual but magnified events, no wrongful act would ever have been committed. Here, too, early detection and proper treatment is the remedy.

As a general rule, insane persons are presumed to be capable of no intent, and hence are not responsible for their acts. But the delusion at the base of their crime, were it a fact, must fully justify the crime. In this way a delusion of a minor injury would not justify a major crime. This distinction is a very fine one. It is more rational to place all his antisocial acts at the door of the mental disorder, and influenced by it, even though the actual connection is not apparent. It is hardly likely that a single mental concept can be affected, without influencing, by association, the others. Likewise, the law assumes a lucid interval, though without a lucid definition of the term, during which the insane person is deemed responsible. This lucidity may be only a relative lucidity, an abeyance or recrudescence in the disease, like the recrudescence after a malarial paroxysm, when the symptoms are absent though the disease is still present. In manic depressive or circular insanity, in fact, it is in the nature of the disease to have these periods of abeyance. The criminal act may be committed on a sudden rise in the cycle of the disease—in the psychopathic curve—or, to use the legal conception, during the nonlucid interval of the lucid interval—and a fall suddenly thereafter.

Responsibility is not a definite entity. It cannot be definitely determined in any case. "Responsibility varies in different individuals, and is never quite eliminated except in the absolute idiot." The rule in the famous McNaughten's case laid down by the English House of Lords, holds that "every man is presumed to possess a sufficient degree of reason to be responsible for his crimes until the contrary is proved and to establish the defense of insanity it must be clearly proved that, at the time of committing the act the accused was laboring under such defect of reason, from disease of the mind, as not to know the nature and quality of the act he was doing, or if he did know it, he did not know that he was doing what was wrong." The better rule is summed up in Lord Branwell's remark: "Could he help it?"

Children below seven are not deemed capable of
FRIEDMAN: THE CRIMINAL IN PSYCHIATRY.

intent; between seven and twelve, it is a question for the jury; after that they are deemed capable or sui juris. Now the juvenile delinquency laws have put all minor offenders in the class of juvenile delinquents, to be kept in custody till majority. In adults a great advance would be made if the question of sui juris would be determined by the psychiatrist or the physician, and not by the jury. For in so much as so large a number of criminal acts are committed by the admittedly insane, and since these acts in the abstracts have not the ear marks of the insane, but in no wise differ from the acts committed by those adjudged sane, the subject deserves more consideration.

Crime is a disease, a social one only it may be, but a disease it is, and as such is a perversion of the normal processes of nature. Crime is moral insanity or deficiency. The moral element of the mind is just as somatic as the intellectual. It is a human, normal quality to realize that a matter is wrong in itself, that it is not in keeping with the standards set by the society of the time. Even without laws the higher individual with the proper moral as well as intellectual development will abstain from an act which on moral analysis is to him a wrong. He who finds justification for his acts only in the law needs yet to develop. It is the continual ability to inhibit propensities which makes the normal. A loss of control of this power, or an unwillingness to control, makes moral disease. Crime is moral insanity in contradistinction to intellectual insanity. But in applying a prepared psych to crime it must be accepted in a broader sense than when applied to those actually recognized as insane. It does not cover merely conditions with apparent confusion. It is a straying from the normal in any degree, or for any time and under any manifestation. "The circles of crime extend from the heavens to the very depths of hell." The circles of crime have their parallel in the circles of mental disorder and defect; both are, at the present time, at least, limitless.

In very early times the mental attitude of the criminal was recognized. "Forgive them, for they know not what they do," was said with a full appreciation of the mental calibre of the criminals represented in the mob. On sounder scientific basis the criminal is a patient. With this patient environment and social conditions play the same rôle as in mental and even physical ills. An individual brought up in an environment where crime is condoned becomes impressed—this word is used in its physical sense—with it and can appreciate no other code of morals. Environment leaves not only a physical impression on the mind but even on the body, as demonstrated by Boas, who showed that the shapes of the skulls of immigrant children changed to conform to the existing types.

Again, crime is due to a distinct psychic disorder, which manifests itself in complete moral perversion, or only along one line—as with the so-called "Raffles." In both instances it may be said to be a paranoid confusion of the mental organs having to do with the moral senses; or it may be due to an entire moral deficiency—in which case the moral centres are crime centres, and the faculty for social harmony is lost. The studies in psycho-

genesis, which place mental disorders at the door of some mental shock, give a definite etiological foundation to many of the psychoses, and makes them amenable to cure by the removal of the shock by psychoanalysis. The psychogenic nature of crime has numberless illustrations in history. Characters such as Hipparchus, Marius, etc., who after years of upright living suddenly turn into beasts of cruelty and crime, are known to have been caused by some reverse or mental shock—which is the psychogenic explanation for their crimes. On the other hand, such geniuses of destruction as Alexander, Nero, Napoleon, etc. were epileptics, and their exploits are explained on the ground of epileptic explosions manifesting themselves in that fashion. Criminals are "psychic epileptics." Similarly, in private life, one hears of individuals turning to crime or debauchery after years of excellent lives. In many instances the psychic reasons are apparent, and even given by the criminal himself,—as injury, financial losses, love, etc. The occasional criminal act or tendency is a moral epileptic manifestation, and the emotional instability as well as the vocational instability of most criminals recall the phenomena of epilepsy.

The instinctive or born criminal is a moral defective, defective from birth or even from prenatal times; one who never had a moral control. The occasional criminal has control at times, yet not very well developed. This control organization has a tendency to become discordant on the slightest provocation. He becomes an habitual criminal when by continually losing this control, the control system becomes so habituated that it can no longer control under any circumstance. These criminals are credited with various characteristics, identifying them as distinct types. The criminal type is still, however, an uncertain quantity. It is not true in all cases. In the majority of criminals who commit crimes of violence and brutality there is a correspondence to an anthropological and psychic average. Those who do not correspond are the standard or average deviations from this standard normal. The fine appearance of some criminals has been ingeniously explained on the ground that these form the "aristocracy of crime," their appearance being a cultivation—a stock in trade—better to carry out their crimes,—the proverbial lions in sheep's skins. The good intellect of many of these moral lunatics or moral imbeciles becomes a dangerous weapon in the hands of these psychic weaklings. Prichard defines moral insanity as "a morbid perversion of the natural feelings, affections, inclinations, temper, habits, moral disposition, and natural impulses without any remarkable disorder or defect of the intellect, or knowing and reasoning faculties, and particularly without any insane delusions or hallucinations." It is a disorder or defect of the moral sense.

The criminal type will be better understood after a thorough study of the psychic, physical, and anthropological characteristics of such individuals. And already various physiognomonic and physical characteristics have been accorded place in this criminopsychic condition. Thus physiognomy has quite a significance in criminology. The instinctive
repulsion felt for certain physiognomonic conformation is merely an expression of racial experience in this regard. Experiments have shown that even young children can distinguish between the photographs of criminals and normals. Yet good faces are found among the bad, and is explained on the principle of criminal aristocracy or exceptionalism in this regard, and vice versa, for yet unexplained reasons. Some criminologists even claim to be able to tell from the physiognomy, the kind of crimes to which the criminal is addicted. It is admitted that in part the criminal faces are imaginary; rather what we expect them to be than what they really are. Physiognomy has a value in crime as well as in many psychic and physical disorders and defects. Nearly all emotions find expression in the face—that is the muscles of the face were intended for by Nature. Inhibition can, in a degree, control the expression of the emotions, but criminals of this type have as little control in this regard as in other matters. Their faces usually betray them. The recognized criminal type is an atavistic degeneration. The present normal is an evolution from the old. The finer feelings and broader sympathies for mankind, as for animals, find egress in the softness of expression in the face of the average normal individual. However, there can be no moral normal, in the sense that there is no improvement, since to carry the moral normal to the extreme would be to end in Utopia or beyond, if we can conceive of that.

Certain bodily characteristics possessed by human beings are now found in the normal in a very rudimentary condition or absent entirely. Lower orders of human society and our animal ancestors possessed these to a marked degree. Persistencies are called stigmata of degeneration. Stigmata of degeneration are well evidenced in the criminally and mentally defective, for which reason criminologists place a special value on them for diagnosis of the criminal tendencies. And while many apparently normal individuals possess them, yet the fact remains that they are more marked and most frequent in the criminal and the mentally defective. Stigmata are said to be atavistic or "teratological" in nature. Among the stigmata of degeneration are the pointed or oxycephalic head, with large face, which is found also in imbeciles and epileptics. This is the "primatoid" type of skull. Asymmetry is a chief characteristic. The large and massive jaws with teeth that fit accurately over each other is characteristic of an inferior race. The palate is saddle or V shaped. The ears are long and voluminous, and have the prominent Darwinian tubercles on their outer margins. Parts of them may be absent. The ability, so frequent in criminals, to move the ears signifies the animal fear and lookout characteristic as well of animals as of criminals. The rectilinear shape of the nose suggests the cretin. The peculiar pallor of the face is indicative of cerebral congestion. (Havelock Ellis.)

Criminals are shorter, lighter, and have smaller musculature, though they are very agile, probably animal fashion—the easier to get away. They are subject to much physical deformity, tuberculosis, and especially sexual anomalies and disorders. It is estimated that about forty per cent. of them are physical invalids. Yet they show a remarkable physical insensibility to pain from any cause, and recover rapidly from even severe wounds. "They lead charmed lives." The more highly developed an individual is, the more sensible does he become to pain or injury. Animals manifest very little. Experiments have been tried in which one side of the body has been made hypnotically insensible, and a wound on it was found to heal more rapidly than on the control side. Insensibility to pain is also a marked feature in idiots, to whom, it is said, pain comes as "a welcome surprise." This condition of physical and mental insensibility best explains the criminal's act of eating and sleeping heartily just before execution, and is not the mental bravery and determination of normal development.

The criminal is ideally lazy. Were laziness made impossible much of the crime would be eliminated. He finds the needed stimulation and activity in the enormous craving and consumption of alcohol. Crime and drink are both morbid manifestations of mental as well as physical disorganization.

As a rule criminals are far below the standard intellectually. Their attention and especially their power of association are poor. Some are densely stupid, and their precocity in the way of criminal cunningness is not intelligence; it is the cunningness of the idiot or the animal, and not an associative creation of a normal. They lack the curiosity of normal mental development. A great number of the inmates of prisons and other punitive institutions have been found positively feebleminded when measured by an intelligence scale, such as the Binet-Simon. Most prostitutes and wayward girls have been found similarly defective, making prostitution merely a manifestation of a moral mental defect. Though social adversity has a part in establishing the system of prostitution, yet it is this adversity which these defectives have not the capacity to meet, since other, but normal individuals living under similar conditions of adversity do not become victims. In the causation of crime, insanity, and prostitution, social and economic conditions are merely psychogenic factors. Criminals and prostitutes may, from lack of intelligence, be unable to engage in other occupations. These ways offer the least resistance—"the easiest way." Here, education and training, as with the moron, will make them self-sustaining, while the betterment of economic and social conditions would eliminate the exciting causes.

Many criminals are intensely religious, yet they must have the fear and not the love of their Creator. Even in this, they emphasize their lack of mental equilibrium, since they cannot see the inseparable relation of the religious and social duties. Besides, blind belief is usually a less difficult mental process than the disbelief born of thought. On the other hand disbelief is, with some, so rabid a belief that it in no wise differs from the former condition. Likewise very few criminals have positive anarchistic beliefs, probably because as an ideal, criminals are incapable of it. The community as a whole needs no archical surveillance. The whole fabric of police organization reaches only the morally defective, who can only, if at all, be kept outwardly moral by this method.
The personality of the criminal and the criminal or antisocial act are manufactured not only by inherent or acquired mental or moral disease or defect, but also by tangible physical conditions. These include almost entirely the sex crimes of violence. Overirritation of the genital apparatus from such diseases as gonorrhea, enlarged prostate, priapism from other causes, etc., are at the root of many of these crimes. The superstition that gonorrhea is cured by contact with a virgin is familiar to all. This then gives one of the best illustrations that crime is caused by disease. In the South it is now being recognized that a major part of the crime of rape committed by negroes is the result of gonorrheal irritation. Likewise irritation of the sexual apparatus may be caused by the loss of restraint over the natural impulses, because of the lack of sexual companionship, enforced by economic conditions preventing or delaying marriage. These acts are the explosive reactions of overrestraint. It will be remembered that in primitive races such causes for irritation are absent. Overindulgence is rare. In fact the savage dances and the like ceremonies are intended as periodic stimulations—a periodicity that is somewhat after the fashion of animals.

In these conditions it is very evident that medical treatment would remove the causes in the physical cases. Progress and accommodation will remedy the social causes. Even in these conditions the individual who will impinge on the rights of others is to a larger or smaller degree morally deficient.

The treatment of the criminal and the elimination of crime resolves itself, broadly speaking, into the lessening or removal of social intemperances of all kinds, whether economic, alcoholic, etc., which are the soil for their development; the treatment of the criminal himself, whether medical or only properly custodial; and the prevention of the transmission by the criminal of the criminal tendency. Crime "is prepared by society, and it is the criminal who executes it; he is without power to disobey." Society as well as the criminal, therefore, needs reformation. And social medicine aims to overcome or correct these conditions, or exclude from the influence of crime or disease, those who would be most likely to become victims of disease or subjects of crime. The hereditary nature of the criminal tendency makes it imperative to treat the criminal of the future in his present day ancestry. This is the subject of eugenics, which now occupies so much prominence in the public eye. The heredity of crime was enunciated in early times—"the sins of the fathers shall be visited upon the children of the third and fourth generations." Yet crime may be transmitted in an ultrahereditary way, through the constant contact of children with their criminal parents, though the children themselves are the dominant descendants of a recessive strain in their lineage. This is the criminal of environment entirely. The removal of such children from their environment will prevent crime in them, just as the removal of children from contact with their tuberculous parents will save them from tuberculosis.

It is urged that the prevention of marriage of the unfit by stricter marriage laws, and the sterilization of the mentally or morally defective, will accom-
genealogically to some more or less remote ancestors, whose recessive characteristic lay dormant in his offspring until awakened, for some unknown reason, in this individual.

Thus far the problem of the criminal has been met largely in the punishment meted out to him. Punishment is the infliction by one individual upon another of some physical or mental hardship, in order that society shall be avenged, that the culprit shall expiate his crime, and that the punishment shall be a deterrent to others. Experience teaches, and on medical grounds it is plain, that since the criminal tendency is still present after punishment, the latter does not effect the purpose for which it is intended. It is a cruelty that should have no place in civilization. Punishment cannot be inflicted humanely, else it would not be punishment.

The mental conception of crime appreciates that punishment cannot be a deterrent because the nature of crime being pathological the criminal cannot prevent it. In the normal individual the deterrent from crime is his own moral conception of the right. The reformations and relapses in crime remind one very strongly of the "lucid intervals" in maniac depressive insanity. Punishment never claims or deters, but adds other grievances or motives for crime; it adds another psychogenic factor to the criminal psychosis.

The shock of prison restraint inflicted on individuals with already impaired psychic organs produces in them the now well recognized prison psychoses or "breakings out." It is believed by some that this condition is a true epileptic manifestation. Prison psychosis usually clears up on the removal of this psychogenic factor—on release from prison. In all likelihood it is the shock of the punishment added to an already existing prepared psyche, which, however, is latent except for the criminal manifestation, which is at the bottom of this psychosis. No doubt the lack of better diagnostic signs makes this condition apparently latent until thus emphasized. It is not alone the prison that is responsible, but the whole fabric of police prosecution of the culprit, from pursuit, capture, "third degree" interrogation, the nerve racking trial, the court setting to sentence, and the incarceration. In this respect the usually lengthy trial is a particular offender. It is here that the legal battles are fought, which though unintelligible to the prisoner add to the strain. Here are hurled the gems of oratory, emotional convulsions take place, together with displays of wit, sarcasms, denunciations, etc., ad libitum. This lasts for days, even weeks. All this is sincerely intended to influence and edify a jury. And, however that may be, it does leave a profound effect on the prisoner which "breaks out" in the reaction from the strain just undergone. The whole subject of prison psychoses has been exhaustively treated in this country by Dr. Bernard Glueck. The association of this apparently new form of psychosis with prisoners exclusively, makes it apparent that crime has an intimate connection with pathological processes in the central nervous system, and especially in the centre controlling the moral perceptions.

The punishment which reduces their own species to the level of the wild beast—to the cell, chain, whip, and slaughter—is repugnant to civilized society, no matter how great the provocation for such treatment. We must treat the criminals as humanely as possible, or else stamp them out as we would insects, without regard to their human character, as was believed by Aristotle. Hospital custodial care should replace the present penal system, trained psychiatrists instead of wardens, and trained nurses instead of jailers. The psychogenic factor, whatever it is, can thus be determined by psychoanalysis, and removed; and the defectives can be treated along modern psychiatric lines. This will return to the fold of usefulness a great number who cannot otherwise be reclaimed. Kindness instead of cruelty should mark the treatment of the moral lunatic or imbecile. Criminals appreciate kindness and sympathy and rarely abuse it. It is not entirely a question of sentiment, since it is more cruel to punish a sane person than an insane one, but a question of strict justice. One who merits a hospital is in a dungeon. One who merits the kindness of society is rewarded with cruelty. How often is a criminal tried and sentenced only to prove so apparently insane that he must be sent to a hospital. Hospital custodial care will protect the public as well as the criminal, and the latter it will cure instead of aggravate. It is the prison life which stimulates the common prison perversions. Prisons manufacture and send to the outer world perversions, immorality, crime, insanity, tuberculosis, etc. If after doing this it kept the victims from society—but no, it seems expressly to manufacture them and, after a longer or shorter period of detention, foists them on the public. The public reaps their harvest for attempting to punish instead of treating this of all human afflictions—crime.

The relegation of crime to the realm of disease would not be more expensive to the community, since the present prison system, coupled with the fact that it reclines none of its inmates is far more expensive than any hospital plan. But before consigning all criminals to the hospital, the latter's patients must be taken to a higher level of care, in order to allow the criminal to slide into the place thus vacated. The abolition of capital punishment would apply custodial care to the intellectually as well as morally insane individuals, with the difference in treatment only one of kind, and possibly, only one of degree.

The law attempts to establish what is an arbitrary way of determining the punishment suited to the crime. On such a basis one crime deserves more punishment than another, without considering the individual committing the crime at all, though a lesser crime may have been committed by an individual of greater depravity. On the other hand, the same sentence may be a greater punishment to one individual than another, depending upon the degree of degeneration of the individual. While dealing with human beings, elastic organisms, the law yet treats them as inanimate bodies. The same sentence for the same crime does not consider the individual who must suffer it. It is almost more logical to revert to the Draconian prin-
ciple that "small offenses deserve death, and I know of no greater punishment for greater ones." This gradation of punishment is admitted even by jurists not to be entirely just. "The measure of culpability and the measure of punishment cannot be determined from the study of the illegal act, but only from the individual committing the act." Either crime and criminals must be treated along scientific, and therefore, just lines, or it is better to heed Aristotle's advice to destroy all criminals as vipers, and not as a means of punishment. Punishment should be changed to treatment, because "punishment is hiring an assassin for a shilling to do what the judge would not have the courage to do." The prison is a moral torture chamber; it should be replaced by a moral hospital for the sufferers from moral disease or defect.

Some advance has already been made by the courts in the prison practice through the establishment of indeterminate sentences, parole and probation systems. In Chicago the courts have attached to themselves trained psychiatrists who aid in preventing the injustice of sending mentally defective or disordered individuals to prison. In the conduct of purely criminal cases the jurists would do better work were they themselves also trained psychiatrists and criminologists, or had they the aid of such persons. The determinate sentence must be entirely replaced by the indeterminate one, the criminal to be detained till cured of his criminal propensity, and released as soon as cured. In prison the criminal must be educated, vocationally and intellectually, along such lines as it is determined he is best adapted—the same as is now done with the moron, who is thus made self-supporting, and taken out of the mass of human debris. Their diseases and defects must be determined and carefully treated. Even cosmetic surgery has a place, for there are few things that make life more dear than the removal of facial disfigurements. On release there must be surveillance, but not police espionage. They must be assisted and advised, and made to realize that society is their friend, not their enemy.

A great deal more improvement has taken place in the treatment of minor offenders than with the adult. The old arbitrary determination of sui juris from the years has been replaced by the juvenile delinquency acts, which place all minor offenders under sixteen years of age in one class to be detained and reformed till majority. But obviously there is still much room for improvement. The juvenile court must not be a sombre chamber, with uniformed attendants, but rather chapellike. Better still, the juvenile delinquent should first be ushered into a psychological laboratory or clinic, where his mental, moral, and physical measurements may be ascertained to determine whether he has any defects, and whether they are of such severity that they need hospital custodial care, or whether they can be treated by the clinic, outpatient method of probation, control, and surveillance.

Until the disease theory of crime is established, prison practice should resolve itself in all cases into the indeterminate sentence, medical treatment, physical, moral, and mental, vocational training along lines most adapted to the criminal, intellecual and social education, and convalescent surveillance after release.

The physician is interested in the subject of criminology, first, because the public as well as the criminal are his patients; secondly, because the physician must fulfill his role of the eternal prosecutor for reform and progress; and finally, because it is the curiosity born of medical training which allows him to delve beyond the merely apparent, no matter where it leads. He is, as an earthly minister, more nearly in real contact with his patient, and can deal not only with his physical ills, but is near enough to deal with his mental, moral, spiritual, and even social ills. Criminal administration must soon slide into the sphere of the psychiatrist, and he should be prepared to receive it. The physician can help to decrease crime by reaching the real causes. He can educate the parents against intemperance and disease. He can raise, by his influence, the standard of social justice, which is such a large factor in the causation of disease and crime, and which is especially so frequently the psychogenic factor in the criminal.

The disposition of the criminal and the elimination of the crime factor can no longer be left to jurisprudence, because it is a nonhuman, blind institution, proudly so depicted. It deals with the realy immaterial, with legal documents, and instruments of restraint and destruction. With these it cannot work out any phase of the human salvation. The training of the jurist is ultraterrestrial, and, thriving on respect and dignity, cannot stoop to earth amid the dregs of humanity and do the good where most of it can be done—"Why should the spirit of mortal be proud?" Only he whose endeavors lead him into the abode of suffering and squalor—a real phase of life—can see where and why crime, insanity, disease, and social vice are manufactured. Only after such experience can we truly say "Judge not!" Crime and its causes cannot be studied nor remedied in black robes, sombre halls, nor with garnet, nor with court criers, but in shirt sleeves. One who, after pronouncing perhaps a very severe and cruel punishment, attempts to preach to the victim is, besides, assuming the prerogatives of Divinity, in the same class as a physician who would censure his patient dying of venereal infection. If we are ever called upon to judge our fellow man, it must be done with a full appreciation of the imperfection of all human beings—"Let whosoever among you who is without fault cast the first stone!"

The judicial conception of crime, no matter how profound, rests on the abstract acts of the criminal. The criminal himself is known only as the inevitable companion of the crime, and not by his personality, or his physical or psychomotoric conformation. To the judicial-police system can be left the ferreting out of those who by their acts come into the class of the criminally inclined, but the diagnosis of the form and severity of this criminal tendency must be left to the medical or psychiatric sciences, which should have the whole matter of the disposition of the criminal. The victim of moral or psychic turpitude, the criminal, must logically be left to the psychiatrist.

SURGICAL ASPECTS OF GRAVES'S DISEASE.*

BY ROBERT E. DAVISON, M. D.,

Pittsburgh.

The thyroid body enclosed in a dense fibroelastic capsule, and firmly attached to the thyroid cartilage and tracheal rings consists of an isthmus and two lobes. Its very extensive blood supply impresses one that it holds an important position in the body architecture. The gland is similar in structure to other compound alveolar glands, and yet, peculiar that it does not possess excretory ducts. The highly vascular capsule dips into the gland dividing it into chief lobules, which subdivide into primary lobules containing acini, or follicles. The lining of the acini consists of a single layer of epithelial cells resting directly on fibrous tissue. There is neither basement membrane nor elastic tissue in the acini. The epithelial lining is the source of two peculiar substances: Colloid and thyroglobulin. The colloid is found within the acini; sometimes filling them, sometimes partly filling them, and sometimes distending them. It is easily stained, homogeneous, and regarded as a proteid although at present the chemical characteristics are uncertain. Its function is perhaps conservative or inhibitory. Thyroglobulin is a hormone; very resistant to the action of acids. The known actions of thyroglobulin prove that it is a potent factor in certain physiological phenomena. It has a dilating effect on the capillaries, as flushing, warmth of skin and excessive sweating; it disturbs metabolism, as loss of weight; and it causes tachycardia.

The pathological entities concerned in Graves’s disease are proliferation, hypersecretion, and degeneration of the thyroid parenchyma. The severity of the symptoms depends upon the amount of absorbed secretion. Speaking broadly the parenchyma increase is in direct proportion to the intensity of the symptoms. In a well marked case the secreting epithelial cells are not only increased in a given acinus, almost filling it, but the acini are numerically increased. The hyperplasia is usually only in portions of the gland. In the patient showing remissions of the toxic symptoms, the gland will show areas of parenchymatous degeneration. The degeneration seems to be due to colloid pressure and epithelial exfoliation. Thyroid secretion is vital to the body and its source is thyroid parenchyma. Excess of parenchyma means excess of secretion. Nature attempts to overcome the excess of secretion by increasing the colloid and by destroying the secreting cells. That nature does succeed at times under a favorable environment cannot be questioned. The basic fault in the gland is parenchymatous hyperplasia. The cause of the proliferation is unknown and is as much a mystery as the cause of fibroid tumors. At the present writing, Graves’s disease should be considered as due to hypersecretion of the thyroid body because of parenchymatous proliferation.

The principal anatomical changes have been pointed out by MacCallum (Medical News, October 9, 1913). Aspects of Graves's disease, as follows: 1. A diffuse hyperplasia of the thyroid gland, with proliferation of epithelium and diminution of normal colloid, the follicles containing a mucinoid substance; the vascularity is usually increased. 2. Hypertrophy and dilatation of the heart with fatty degeneration. 3. A severe fatty degeneration of the voluntary muscles, evidently toxic in origin.

In addition the orbital fat is increased; the lymph glands, thymus, and spleen often show lymphoid hyperplasia. The four cardinal symptoms of Graves’s disease, namely: tachycardia, tumor, tremors, and exophthalmos are rarely all present in a given case. Tachycardia is constant and is usually first recognized. It is a valuable symptom and found early in the disease. A quick pulse without apparent cause invites investigation. The proportion of males to females afflicted is about one to eight, and most commonly found between the ages of sixteen to forty. Enlargement of a part of the gland is fairly constant but enlargement of the whole gland is comparatively rare. To the casual observer or even to the patient, the enlargement might not be apparent but to the initiated it is usually demonstrable. Cough, hoarseness, or stridor is sometimes caused by an enlarged lobe deeply embedded in the neck. Properly to palpate the gland the neck must be exposed and the neck muscles completely relaxed. Often a suggestion of enlargement is seen in the prominence of the sternocleidomastoid muscle. Tremor is not constant, and when present denotes either an acute phase or an advanced stage of the disease. It may be demonstrated by the patient’s attempt to join the finger tips while the arms are in extension. Treatment is of little avail when muscular tremor is present in an advanced stage of the disease.

Exophthalmos is rather a late symptom, and as a rule, the disease should be recognized before this symptom appears. Nervousness, insomnia, and dysmenorrhea in women, are frequently present. When the nervous phenomena predominate there is often present a psychopathic element, and this type of patient is very little benefited by treatment. Vomiting and diarrhea, ascites and edema are late symptoms due to cardiac degeneration. The writer would call your attention to the following observations: 1. That Graves's disease runs a protracted course; 2. that acute Graves's disease is only apparent; 3. that there are acute phases which are only a flaming up of a chronic affection; 4. that there are latent phases in which there is a remission of symptoms with a general improvement of the patient’s health; and 5. that this tide like rise and fall of the symptoms is characteristic and demonstrable if the case has been observed for a reasonable length of time. Indeed the pathological findings in the thyroid gland should prepare one to expect a changeable syndrome. Hyperplasia and degeneration go hand in hand, perhaps, not in the same acini but in the same lobe. One can readily see how 'natural cures' take place; just how often in a given number of cases the author is not in a position to state. However to destroy just enough secreting cells to bring the total gland secretion to the normal requires a nice adjustment of nature.
The diagnosis of Graves’s disease is easy in advanced cases; most of these, however, are beyond cure. Extrathyroid pathology has already taken place, and usually in the heart muscle. There are two types of these advanced cases in which the prognosis is bad. 1. A rapid intermittent pulse, a low blood pressure, ascites, edema of the extremities, diarrhea, vomiting, and emaciation: and, 2. where the patient apparently is overwhelmed by an excessive absorption of thyroglobulin—flushed skin, the face and lips puffed, and a deep red in color, rapid pulse, the blood pressure becoming progressively lower as the pulse gains in rapidity, high temperature even to 106° F., gastrointestinal symptoms and delirium. “The easier the diagnosis the worse the prognosis.” It is the incipient, the early case, not necessarily measured by time, but by the progress of the disease, that has inspired the writer to offer this paper. No single symptom is pathognomonic; the syndrome is the key which unlocks the diagnosis, and there is no way to pick up the aggregate other than by tabulating each individual symptom. In a suspected case the writer places the patient in a hospital for observation. Respiration, temperature, and pulse rate are noted every three hours night and day. A careful physical examination is made, paying particular attention to the heart and lungs. The blood pressure is noted. In the blood examination, the hemoglobin, red blood cells, total leucocyte count, and a differential white count are considered. In a positive case the mononuclear leucocytes are usually increased. The variations in temperature and pulse are significant. Most of my cases showed a Flint heart murmur. The urine is tested both chemically and microscopically. Uneven tension and irregularity of the pulse denote myocardial changes, and frequently dilatation. Puffiness about the ankles is not uncommon. A good case history must be written, because on this you will depend when you come to determine whether the disease is acute or latent. In brief, study your patient assiduously, paying no attention to naming the disease until you have built the syndrome. Usually three days in the hospital will suffice, but if tuberculosis or syphilis or some other disease becomes suspicious, then the time must be extended in order to apply the tests.

The writer offers no treatment for advanced Graves’s disease with end pathology, because he believes that treatment is alleviative and not curative in this type, and internal medication offers more to the patient than any surgical procedure. Hence, this discussion applies only to early cases.

The purpose of treatment is to lessen absorption of overproduced internal secretion of the thyroid body. Nature’s method is by attacking the secreting cells by degeneration, or destruction of the parenchyma. Therefore, following Nature’s plan, a safe treatment that will destroy a part of the parenchyma should give curative results. The surgical procedures most popular at present are: (a) Application of x rays, (b) injection of hot water, and (c) partial thyroidectomy; all having a reasonable basis, and each producing cures. The first two are not desirable because they are hidden operations, with uncertain results, and too many unknown factors. Surgery demands precision, known factors, definite results, and open procedures. The third method satisfies all these requirements and will give the most uniformly good results. Partial thyroidectomy, in an early case and in the hands of a good operator, is not, per se, a dangerous operation ranking in mortality a little above minor operations. It is best to operate in the latent phase.

Frequently the physician is consulted when the disease is in its acute phase, because the symptoms are very alarming to the patient. The question arises what should be done. A partial thyroidectomy should not be done at this time, because overactivity means toxemia, and a toxic patient is a bad surgical risk. Then anoci association, as brought forward by Creile, must also be considered. The patient should be put to bed at absolute rest and quietness, away from inquisitive friends, an ice bag to the neck and alleviative medical treatment given. Very often this will suffice to bring about a latency. However, if latency is tardy and the patient is apparently in imminent danger of being overwhelmed with thyrotoxine, then ligation of one or more thyroid vessels would be indicated, which promptly produces latency. The administration of the serum advocated by Rogers and Beebe is said to act promptly. The writer has had no experience with the serum, and he cannot advise its use.

To formulate a rule defining just when to do a thyroidectomy in Graves’s disease is nonsense; good judgment is a requisite, and this comes only with experience. This experience does not necessarily mean a great number of cases, but it does demand an intensive study of patients. The dernier ressort operations in Graves’s disease are failures.

In conclusion, “The earlier the patient is seen and the less distinct the indication, the more elaborate and painstaking should be the investigation and the more careful the preparation. We may state, therefore, that in the earlier stages of surgical lesions the diagnosis is the major part of surgery; the operation is minor. It is expert and delicate surgery, nevertheless, and the immediate and ultimate results are the best. In this stage, treatment is the test of the diagnostic technic.”

(Bloodgood, Journal of the American Medical Association, lii, 12, p. 911.)

A STUDY OF THE ACTION OF OXYGEN, HYDROGEN DIOXIDE, AND OZONE GAS UPON THE GROWTH OF CERTAIN BACTERIA.*

By S. E. Finch, M.D., New York.

The physiological and the mechanical action of oxygen gas when introduced within the peritoneum of normal animals and of man, was found by Bainbridge (1) and by Meeker (2), “to justify the assumption that the intraabdominal use of oxygen is

*From the Research Laboratory of the New York Skin and Cancer Hospital.
entitled to a place in surgical therapy." The beneficial effects obtained by the use of ninety-five per cent. oxygen intra-abdominally in the human subject following severe laparotomies, (3) in particular, the favorable progress of certain cases with associated local or general intraperitoneal infection in which it was used, raised the question as to whether or not an antiseptic action is included in the therapeutic action of oxygen. At the suggestion of Dr. W. Seaman Bainbridge, a study of the action of oxygen upon the growth of certain microorganisms was undertaken in the laboratory of the New York Skin and Cancer Hospital. The results obtained with oxygen led to a study of the bactericidal action of hydrogen peroxide and of ozone. The microorganisms used were virulent strains of auroccoccus, Streptococcus brevis, Bacillus coli, and one strain of the Bacillus tuberculosis (human type).

**TECHNIC.**

The culture media used for growing these bacteria were meat infusion, glycerin, and serum agar, plain and glycerin bouillon. When it was desired to grow them in an atmosphere of oxygen, the organisms were grown in litre and half litre flasks on solid media. For use with a continuous current, they were grown in test tubes and in flasks in fluid media. Where suspensions of the bacteria were required, several slants of one strain of an organism were grown for twenty-four hours at 37°C. and the growth washed off from each slant with two cubic centimetres of sterile water and transferred by a sterile pipette to a large sterile tube; the bacteria in this tube were thoroughly emulsified, and two cubic centimetres of this suspension regarded as representing one culture in conducting the experiments.

To keep the different strains of bacteria that were employed, virulent, they were passed through mice or guinea pigs at frequent intervals.

The oxygen gas used represented ninety-five per cent. of pure oxygen. The oxygen was employed at 22°C. when used as a continuous current and for replacing the air in flasks. For the latter purpose oxygen was led from its tank through sterile apparatus, introduced just above the surface of the medium in the bottom of a flask and allowed to flow until from five to six litres had thus entered the vessel at the lowest point possible, with free exit for the gases at the top. In each instance before connection with the oxygen tank was severed, screw clamps, securely fastened on the heavy rubber tubing leading to and from the vessel, rendered leakage impossible.

The hydrogen dioxide (U. S. P. three per cent.) was obtained from two different sources of manufacture, and for each group of experiments was taken from freshly opened bottles. All apparatus for this work was sterilized previous to use. Twenty-four hour fluid cultures, and suspensions of twenty-four hour slant growths, as described above, were used, and the peroxide added directly to the tubes. When testing the viability of an organism, subcultures were made every thirty seconds until no further growth was obtained and subsequent incubation showed the microorganism to have been dead.

Ozone was first generated in the laboratory by passing oxygen through a Siemens's tube and supplying the current and necessary voltage by means of batteries and induction coil. Later a single unit ozonizer (Gerard) was used and higher concentrations of ozone were made available. This ozonizer was built for ozonizing air and had a drier attached; however, by disconnecting the air pump and connecting with an ozone tank, oxygen could be ozonized. Four factors influenced the concentration of ozone obtained with each apparatus: 1. The percentage of oxygen in the gas ozonized; 2. The rate at which the gas was passed through the ozonizer; 3. The electrical discharge and its potential; 4. The condition of the gas as regards temperature and moisture. With the Gerard apparatus the fixed factor was the third, the others were known and controllable; with the Siemens's tube the third factor was variable, influencing the output of ozone. The maximum concentration with the latter apparatus when working satisfactorily, was 0.001 per cent. by weight of ozone at 22°C. With the single unit ozonizer, the proportion of the ozone by weight could be varied between 0.005 and 0.012 per cent. when air was used, and between 0.015 and 0.015 per cent. when oxygen was the gas ozonized. While using air the maximum amount of ozone that could be generated per minute at 22°C, was 15.6 milligrams; while using ninety-five per cent. dried oxygen the maximum amount that could be generated per minute at 22°C, was twenty-four milligrams. To secure dilutions between the 0.001 per cent. (first apparatus) and 0.005 per cent. (second apparatus) it would have been necessary to use large quantities of oxygen and to pass the gas quite rapidly over the electrodes; but, aside from the waste of oxygen entailed, the rate of flow of the gas was too rapid for convenient use in connection with the experiments. The test employed for estimating the amount of ozone in a given specimen was the one ordinarily used, passing a known volume of gas through a neutral solution of potassium iodide, acidulating with sulphuric acid, titrating the iodine with sodium thiosulphate, using starch solution as an indicator. For the work with ozone all tubing had to be of glass or of special aluminum make, and all corks and joints rendered free from leakage by means of electrician's tape or paraffin. To approximate the intimate manner in which oxygen could be passed through a suspension of bacteria in a test tube (i.e. by passing the oxygen through a sterile hard rubber tube having many fine perforations in its sides near the end), wash bottles with specially made double glass stoppers were used; these permitted the ozone to enter at the lowest portion of the suspension from a glass bulb in which there were several fine perforations, with free exit for gas from the bottle through the outer cork.

**OXYGEN.**

Each one of the four microorganisms was grown on solid media in litre and half litre flasks, and the atmosphere in each flask replaced by one of ninety-five per cent. oxygen. The flasks, when rendered free from leakage, were kept at 37°C. Control flasks containing air were likewise rendered free from any external gas interchange and kept under the same conditions. Growth in the flasks con-
taining oxygen seemed in each instance as luxuriant as in the control flasks. Different flasks were inoculated with the four different microorganisms and before visible growth had taken place their atmospheres were replaced by oxygen. These showed variable times of appearance and rates of growth for the first forty-eight hours in the aurococcus flasks, but good growths in all other flasks, the growth frequently being macroscopically visible in one of these flasks before that in the corresponding control. It may be observed here, that, using fresh media containing considerable moisture, the tubercule bacillus seemed to grow as readily in the presence of oxygen as in the presence of air in the controls; but, given dry media and dried oxygen, growth could be inhibited while these conditions existed.

Fluid cultures of any of these bacteria, before incubation, were subjected to a continuous stream of oxygen for twelve, twenty-four, and forty-eight hours and showed at the end of these periods luxuriant growths in all tubes except those containing the tubercule bacillus. Here, there was an absence of any visible growth when the oxygen had been passed continuously through the suspension in the form of numerous fine bubbles. Incubation of the tubes after discontinuing the oxygen, however, showed the bacteria to have been simply inhibited in their growth and not killed. The aurococcus cultures appeared bleached but regained their normal color upon discontinuing the oxygen and transplanting into fresh media. Aside from this bleaching of the aurococcus and the absence of growth under the conditions mentioned in the tubes containing the tubercule bacillus, there was no effect observed upon the growth of any of the other bacteria. The streptococcus and the colon cultures not only remained viable, but grew luxuriantly while being exposed in fluid media to a continuous current of oxygen.

The results obtained by oxygenating freshly transplanted fluid cultures of these bacteria led to the oxygenating of sterile water suspensions. Fractions of a culture were used—finally one seventh of a culture. The colon bacillus and the streptococcus could be as easily subcultured as their controls at the end of forty-eight hours' exposure to a continuous current of oxygen; the aurococcus invariably showed fewer colonies developing on subculture from the oxygenated suspensions than from the controls. Cultures from the tubercule bacillus showed latent growth as compared with cultures from its control suspensions. The aurococcus was subjected for another twenty-four hours to the stream of oxygen, at the end of which time, seventy-two hours, no growth was obtained on testing for viability, whereas light growths of aurococcus could still be obtained from the controls.

The action of ninety-five per cent. oxygen on any of these microorganisms in the presence of culture media did not demonstrate it to be bactericidal in any instance, and only in the case of one organism—that of the tubercule bacillus—did it inhibit growth; i. e., when the bacteria were freshly transplanted into fluid media and subjected to the action of the oxygen in a continuous current passed through the culture. Discontinuation of the oxygen and further incubation renewed the growth of the bacilli.

In the absence of organic matter, on the other hand, oxygen used as a continuous stream of fine bubbles passed through a freshly suspended fraction of a culture in sterile water, proved inhibitory to the subsequent growth of the aurococcus and the tubercule bacillus. In the latter case the tubercule bacilli in suspension had to be first thoroughly emulsified, as the presence of bacilli in clumps in the suspensions seemed to protect those within the clumps. No influence on the viability of Streptococcus brevis or of Bacillus coli was observed upon similar subjection to oxygen for forty-eight hours. With prolonged use of the oxygen, i. e., for at least seventy-two hours or until such time as the gas had been brought into intimate contact with the bacteria in suspension, no growth or subculture could be obtained with the aurococcus. Control suspensions could be subcultured but had not been subjected to continuous agitation by means of a current of sterile air.

**HYDROGEN DIOXIDE.**

The results with this oxidizing agent varied with the two different makes that were used, though both were labeled, "U. S. P. three per cent." For convenience they will be designated as (A) and (B). Employing suspensions of the bacteria in sterile water, the amount of hydrogen dioxide (A) which would kill one culture of the aurococcus in five minutes, when added to it, was one third of the amount required when using the hydrogen dioxide (B). The amount of hydrogen dioxide (A) which would kill one culture of either Streptococcus brevis or Bacillus coli in five minutes was just one half the amount required of the hydrogen dioxide (B). Any fluid culture of any one of the different bacteria could be killed within the same length of time—five minutes—that was required to kill suspensions in sterile water, but never with as small amounts of the hydrogen dioxide as proved sufficient in the suspensions. The same was true with cultures on solid media, greater amounts were required to kill a given culture than when in aqueous suspension; and proportionately greater amounts of the hydrogen dioxide (B) were necessary than of hydrogen dioxide (A). Apparently part of the oxidizing agent was reduced by the media.

**OZONE.**

Passing from hydrogen dioxide to ozone—an other oxidizing agent, from which nascent oxygen is derived at the moment of its liberation in the atomic state—results with its use were dependent entirely upon the intimacy and rapidity with which it could be brought into contact with the bodies of the bacteria suspended in fluid media. With the first apparatus used for generating ozone, the Siemens's tube, though the proportion of ozone by weight in the ozonized oxygen was never greater than 0.001 per cent., suspended cultures of the four different microorganisms could be killed if exposed to its action for a sufficient length of time. Or, in other words, the passage of as many litres of this strength of ozone through a culture (suspended in sterile water) as would represent at the maximum the use of 37.5 milligrammes of ozone, was sufficient to kill any one culture of bacteria. Twenty milligrammes was the smallest amount, with this
concentration, which was ever found to kill a culture. When the use of greater concentrations of ozone was possible, as with the single unit ozonizer, any one culture of the aurococci, Streptococcus brevis, or Bacillus coli could be killed by two minutes’ exposure to ozonized air containing 0.012 per cent. by weight of ozone; or could be killed in one minute by exposure to ozonized oxygen containing from 0.015 to 0.0185 per cent. of ozone with an unused surplus of ozone invariably remaining, as shown by tests for ozone in the escaping gas. Ozone gas, whether used at 22° C. or with its temperature raised to 33° C., seemed to give equally good results as regards the rapidity with which the bacteria could be killed, once the ozone was brought into intimate contact with them in fluid suspension; less ozone being required in the absence of organic matter.

Cultures on solid culture media could be killed by using greater amounts of ozonized air or ozonized oxygen. This was always, however, a difficult procedure, as more ozone escaped from the vessel than was reduced by the bacteria and the media. Invariably subcultures could be obtained from the centre of colonies and from that portion of growths next to the surface of the media, long after those from the periphery and surface of the colony had ceased to grow on transplantation. Only by the use of ozone in high concentration and under pressure could bacteria within a solid medium be reached and killed by the gas.

Ozone proved to be an active bactericide in vitro for all the microorganisms used, provided certain conditions were fulfilled. The bacteria had to be in fluid culture or in suspension in a fluid medium such as water, and the gas had to be passed through the suspension or medium rapidly, in the form of numerous fine bubbles. It was necessary to break up the heavy film growth of the tubercle bacillus to secure the rapid oxidation of the latter. Ozone had no selective action as regards these bacteria in the presence of organic matter, such as that contained in the culture media used. To kill one culture of any of the bacteria in sterile water suspension, the maximum amount of ozone used was 37.5 milligrammes (0.007 per cent. strength), the minimum, twelve milligrammes (0.005 to 0.012 per cent. concentration). To kill one culture in a fluid medium of any of the bacteria mentioned, the maximum amount of ozone used was 70.5 milligrammes, the minimum twenty milligrammes.

CONCLUSIONS.

1. Oxygen in its molecular form O2, ninety-five per cent. pure, does not kill or inhibit the growth in the moist state of Streptococcus brevis or of Bacillus coli.

2. Oxygen may inhibit the growth of the tubercle bacillus when brought into intimate contact with each microorganism in the moist state, but does not kill it.

3. In the absence of culture media (organic matter), oxygen inhibits the growth of the aurococci, and may kill it, after prolonged and intimate contact with each microorganism in the moist state.

4. Hydrogen dioxide (U. S. P. three per cent.) is an active bactericide for the four microorganisms tested. The action is dependent upon the amount of the hydrogen dioxide used, the age of the preparation, its strength, and, also upon the presence or absence of readily oxidizable organic matter.

5. Ozone (ozonized air or ozonized oxygen) under certain given conditions is an active bactericide for the four microorganisms used. Its action is dependent upon its concentration and the intimacy and rapidity with which it is brought into direct contact with the bodies of all the bacteria in suspension in water or fluid media.

6. Ozone does not dissolve in sterile water, or in saline solution in more than faint traces; therefore its bactericidal action is dependent upon its passage through these solutions or through any fluid medium as a continuous stream of numerous fine bubbles of gas.

7. Ozone has no selective action for any of the four bacteria in the presence of organic matter.

REPORT OF A CASE OF CARCINOMA OF THE FACE.*

By Edwin S. Maxson, A. M., M. D., Syracuse, N. Y.

I wish to report a case of carcinoma of the face that came under my observation in 1910 and 1911. The patient was the faithful nurse who cared for my mother during the last months of her life. The patient has been seen by some of the members of the Syracuse Academy of Medicine; but, I believe, her case has never been reported. I recorded her history on July 21, 1910, a portion of which I will give here.

The patient, Mrs. D., was forty-one years old, American born, and a practical nurse and housekeeper by occupation. Her father died of a ‘chronic diarrhea’ at about sixty years of age. Her mother died when Mrs. D. was a very young child. Neither the cause of her mother’s death, nor the age at which she died, was known to the patient. One of the patient’s brothers and three sisters are living. One brother died of diphtheria.

Mrs. D. had diphtheria when she was a small child and again when she was about nineteen years old. Her health in adult life was generally good. At the time this record was taken she appeared to be in excellent health. Mrs. D. had had two children; both of whom were living.

She worked for about three years as nurse at the Rome State Custodial Asylum, handling patients suffering from all diseases. She did private nursing also.

About four or five years before this record was taken the patient first noticed an occasional peculiar numb feeling in her right cheek, coming on while lying down at night. She nursed a case of diphtheria in March, 1909. A year later, during the spring preceding this examination, she had an aggravation of the numb sensations in her cheek at night. She then had what she described as “cold chills” in her right cheek. For most of the time during the preceding year she had a thick, yellow discharge from her right nostril. For about five weeks before the time of this record, she noticed that her upper dental plate hurt her jaw on the right side, this tenderness growing worse.

She was examined by Dr. Thomas Halsted about July 14, and again on July 19, 1910. Doctor Halsted found polypi and some other pathological tissue in the right

*Read before the Syracuse Academy of Medicine, October 7, 1913.
nostril. The right antrum was also affected. After his first examination, Doctor Halsted expressed the opinion that the disease was malignant and was carcinoma. However, upon his request, Doctor Jacobson also examined the patient July 26th, and expressed the opinion that the disease was sarcoma.

In accordance with Doctor Jacobson’s advice, Doctor Halsted removed some of the pathological tissue from the patient’s nostril and sent it to Doctor Steensland at the medical college for examination. Doctor Steensland found the tissue to be carcinomatous and thought that the patient might live, if not operated upon, for about one year. This proved to be a fairly accurate prophecy, as the patient died ten months later.

About one month after Doctor Halsted made his first examination, the tumor broke through and began discharging from the antrum into the mouth, between the cheek and the alveolar process of the jaw. There was considerable pain and eventually, also considerable swelling in the right cheek. However, the nightly application of belladonna ointment, under sterile cotton and a bandage, gave much relief from the pain.

I will say that the tumor, much to my satisfaction, never broke through the skin of the face. On the other hand, the pathological growth crowded down from the antrum through the roof of the mouth, eventually filling a considerable part of the mouth and finally preventing the closure of the jaws.

To afford temporary relief to this condition, Dr. George M. Price, on the Horse of the Hospital of the Good Shepherd, performed a skillful operation, removing a portion of the carcinomatous growth. This operation, performed two weeks before the patient’s death, permitted the closing of the mouth and facilitated breathing and the taking of liquids, besides accomplishing much in anesthetic way.

Some surgeons might have resorted to an early operation, removing a considerable part of the upper jaw on the right side, but I was glad to have the patient (who died at our home) live as long as possible, and so was better satisfied without the early operation.

I have sometimes wondered whether Mrs. D. might not have introduced cancerous cells into the nostril while nursing at the State Custodial Asylum in Rome.

818 Madison Street.

ACUTE PELLAGRA OR DERMATITIS EXFOLIATIVA?

Whether the case below was due to pellagra (as I think) or to septic dermatitis, I think it sufficiently interesting for publication.

History. A youth of twenty years, who was up for the Territorial Annual Training in Jamaica last summer, York, came to me on September 8th for treatment. He was an employee, clerk at Newcastle-on-Tyne post office. He complained of much headache, constipation, anorexia, oral sepsis, foul tongue, and great lassitude. Naturally I thought of toxemia or enteric fever, amebaluria or paratyphoid. There was an indistinct erythematous papular brick red rash without intense itching upon the sun-exposed surfaces of the forearm, face, and neck—this later on spreading to chest and other parts. On September 17th he was evidently very ill, temperature 101° F., pulse 100, respiration 20. He was ordered to bed which he had remained until present date. He had contracted pediculosis pubis and used blue ointment liberally, which undoubtedly produced an irritating rash about nates, pubis, and inner side of thighs.

Symptoms. Seriously ill with dermatitis and desquamation, which became very profuse and flaky; the skin of pelvis and feet peeled off en masse. Neuritis appeared with tremblings of upper extremities, some dullness of vision (afterward corrected). Noystagmus. Urine specific gravity 1.020; acid reaction; no albumin nor sugar. Suspecting Bacillus coli and either or both staphylococcus and streptococcus, the urine was examined microscopically and found to contain two forms. This was repeated later, two or three times with the same result. Urine (diluted 1:10) now soon began to appear, the papules having become vesicles, then pustules, ultimately cellullitis. Then he began to lose weight, but was rational and cheerful except when his temperature reached 107° F. Then, of course, he was delirious; afterward he commenced to be despondent—costive throughout. A Gruber-Widal test was made with negative result. On October 3rd, to still further complicate matters, he had stomatitis, followed by dirty white patches on tonsils and fauces; a bacteriological examination was made; result negative, no Bacillus hofmanni, only Staphylococcus aureus and casts present. Supersensitiveness well marked and reflexes normal. Pur exuded (still continues up to date) all over the body in crabs, disappearing and reappearing—very foul and stinking.

Treatment. External: Boric acid and fifty per cent. cresol washes, lotio carbonis detergens and calamine, tuberculin, zinc oxide ointment, hydro wool, per trolatum, and powdered boric acid. Internal: Mistura alba (B. P. C.), cum cerasa, calomel pro re nata, hexamethyleneamine with acid phosphate of soda, and stimulants. On October 8th the patient received an injection of Staphylococcus aureus vaccine, on October 10th he was given an injection of Bacillus coli vaccine, and on October 15th an injection of autogenous vaccine, prepared from the pimpls of the patient, which was to be given twice weekly. The pigmentation turned brown.

Remarks: My theory is that this poor fellow may have drunk water from a shallow brook (great drought here all last summer) and either been bitten by the fly or swallowed the ova, etc., of the simulium. Again, could meat have been affected by it? I think not, or others would have been affected, too.

The opinion I expressed to relatives of patient at the first was, that bacilli had poisoned his system, producing septicemia, with the bare possibility of enteric fever. Now I had first to exclude scarlatina, urticaria, and syphilis, and later to eliminate typhus and enteric fevers, and tuberculosis. At the third week I began to think it might be an acute case of pellagra, which disease I had never seen, but always read of as chronic. Two doctors said, clinically, absolutely pellagrous, but the bacteriologist has not yet found the simulant Bacillus. Although urine, pus, and stools were examined. Mark the dermatitis, profuse desquamation (deceased yet), erythema, pigmentation, the suppuration and intense excretion of stinking pus by rotten cellullitis, the extreme enaciation, and now pyemia! This puzzling case gives rise to the following questions: Was the dermatitis pellagra? Was the dermatitis simple dermatitis exfoliativa? Was the dermatitis due to sepsis? Was the sepsis due to dermatitis?

Doctor Patterson, skin specialist here, thought it a case of simple dermatitis exfoliativa with sepsis, but he did not see it for many weeks after commencement.

My thanks are due to W. Leech, assistant sur-
geon to Newcastle Infirmary; Doctor Kerr, medical officer of health, Newcastle; Prof. H. J. Hutchens, D. T. O., pathologist; Doctor Hemmrough, medical officer, Northumberland County; Doctor Slade, pathologist and bacteriologist, and Dr. D. Wells Patterson, physician to the Skin Hospital, Newcastle-on-Tyne.

435 WESTGATE ROAD.

**Therapeutic Notes.**

**Treatment of Pseudomembranous Dysmenorrhea.**—A. F. Plaque, in *Bulletin medical for May 3, 1913*, states that prompt benefit can often be obtained in this condition by seeking for and overcoming disturbances relating to distant parts of the body, gastric dilatation due to rapid eating, constipation, excessive social or scholastic activity, carrying heavy weights, exposure of the feet to cold, etc. Sometimes the condition has been overcome by applying a five per cent. solution of cocaine hydrochloride to the genitonasal surface, situated on the anterior turbinate and septum nasi, and if benefit is noted, later cauterizing these points. As antispasmodic remedies, potassium bromide, zinc salts, ammonium valerate, and the expressed juice of fresh valerian, are most favored. A pill containing zinc oxide and the extracts of valerian and hyoscyamus (0.05 gram), or four-fifths of a grain of each of the last two is very effective. Tepid baths, and particularly special thermal cures, are useful to suppress nervous excitement and menstrual pain.

At the time of the painful attacks enemas consisting of a half litre (one pint) of a lukewarm decoction of marshmallow root to which twenty drops of laudanum have been added may be used, but morphine injections should be avoided. Enemas containing 0.5 gram (7½ grains)—later, one gram (15 grains)—of antipyrine also act well. Antipyrene suppositories may sometimes induce slight rectal irritations; then other calming agents may be used, e. g.:

R  Extracti hyosciam., \( \frac{1}{2} \) gr. v (0.3 gramme)

Fiant suppositoria No. vi.

Vaginal tampons impregnated with glycerin to which belladonna or antipyrine has been added act more directly upon the cervical spasm. Poultices sprinkled with laudanum, hot and moist compresses covered with an impervious material, or alcoholic dressings similarly covered may be used to relieve pain in the lower abdomen, while irritating applications over the skin on the inner aspects of the thighs will facilitate the discharge of blood.

Emmenagogues should be employed only in small, fractional doses, the reaction locally being meanwhile kept under watch. Viburnum prunifolium and gossypium are regarded as sedatives for uteroovarian pain. Gossypium appears to be especially suitable where there is both a painful and an abundant menstrual flow, and may be given in divided doses amounting to from 45 to 90 grains (3 to 6 grammes) a day. Roël often combines hydrastis with it, as in the following formula:

R  Fluidextracti hydrastis, \( \frac{2}{3} \) ss (5 grammes)

Fluidextracti gossypii radicis (U. S. P., 1890), \( \frac{1}{3} \) ss (1.5 grammes); Fluidextracti viburni folii, \( \frac{1}{3} \) ss (1.5 grammes)

Cinnamomi saigonici, \( \frac{1}{3} \) gr. iii (0.2 gramme)

Vanillae, \( \frac{1}{3} \) gr. i (0.06 gramme)

Aloes purpureae, \( \frac{1}{3} \) xv (50 grammes)

Alcoholis, \( \frac{1}{3} \) ss (50 grammes)

Syripi, \( \frac{1}{3} \) ss (50 grammes).

M. Sig.: One to three teaspoonfuls to be taken for a week preceding the expected advent of menstruation, as well as during the period of pain.

Where there is a mechanical obstruction to the evacuation of blood, the foregoing measures can only be palliative. Stenosis of the cervix is a frequent cause of pseudomembranous dysmenorrhoea, and should be treated by dilatation with the aid of a laminaria tent, followed by injections of iodine, silver nitrate or zinc chloride solutions. The laminaria used should previously have been soaked for twenty-four hours in:

R  Cocainae hydrochlori, \( \frac{1}{3} \) gr. viiss (0.5 gramme)

Iodoformi, \( \frac{1}{3} \) gr. lxxv (5 grammes)

Aetheris, \( \frac{1}{3} \) iv (90 grammes).

Fiant solutio.

It should be allowed to remain in situ only twelve hours.

**Medical Treatment of Salpingoöophoritis.**—A. Robin, in *Nouveau remèdes* for June 8, 1913, is stated to recommend in acute inflammation of the uterine annexa, hot moist applications, with or without the following liniment:

R  Extracti opii, \( \frac{1}{3} \) ss (4 grammes)

Extracti belladonnæ foliorum, \( \frac{1}{3} \) ss (4 grammes)

Extracti hyosciam, \( \frac{1}{3} \) ss (4 grammes)

Chloroformi, \( \frac{1}{3} \) ss (20 grammes)

Oleæ olivæ, \( \frac{1}{3} \) ss (80 grammes).

Misce. Fiat linimentum.

The patient should be kept absolutely quiet in bed in the horizontal position. If the temperature is high and the pain severe, local blood letting by means of wet cupping or leeches should be practised. Injections of hot water also constitute a useful measure. The receptacle should hold two litres of water and must not be over eighteen inches above the level of the bed. The water, previously boiled, should be introduced for a period of five or more minutes, and at a temperature of 45° C. (113° F.), increased on the succeeding day to 50° C. (122° F.), or even to 55° C. (131° F.). Two teaspoonfuls of tannic acid, from forty to sixty drops of the tincture of opium, and later from ten to twenty drops of the tincture of iodine may be added to the two litres of hot water. After the vaginal douche a rectal injection should be administered of 250 c. c. (one half pint) of hot water, gradually increased to 500 c. c. (one pint). The intestinal functions should be watched throughout, castor oil being given in the morning if indicated.

In cases of annexal inflammation of the chronic type, in addition to hot rectal injections, vaginal tampons previously dipped in equal parts of glycerin and tannic acid should be employed. The tampon should be left in about three hours, and renewed every day, or on alternate days. Radical treatment
may yield very happy results in these patients. Where the affection is in the "cold" stage, massage of the uterus may prove useful. In depressed or anemic patients some iron preparation should be ad-
ministered, and if the residual cicatricial tissues are being only incompletely absorbed, the following combination is advised:

- Potassii iodi, ............ gr. lxxv (5 grammes);
- Sodii arsenatis, ............ gr. ¼ (0.05 gramma);
- Aquæ destillatæ, .......... 5x.

M. Sig.: Two tablespoonsfuls a day.

Symptomatic treatment includes, for example, the relief of pain, which may be combated by the ad-
ministration of enemas of a 0.5 per cent. solution of antipyrine. For the insomnia the author uses sul-
phonal in seven and one half grain (0.5 gramma) doses, taken in the evening two hours after supper. In the presence of mild fever, the author prescribes:

- Quinine hydrochloridi, . . . . . gr. vii (0.45 gramma);
- Digitalis folii pulveris, .... . . gr. ¼ (0.05 gramma).

Fiat cachetæ No. 1.

Sig.: To be given four hours before an expected rise of temperature.

In more pronounced fever one of the coal tar drugs may be administered, and in very high fever, intramuscular injections of metallic ferments.

To allay vomiting, two drops of the following solution may be given three times a day:

- Morphine hydrochloridi, . . . . . gr. iss (0.1 gramma);
- Aquæ laurocerasi, .......... 5s (2 grammes).

For rectal tenesmus, an enema of gelatin may be employed:

- Gelatini, .................. gr. lxxv (5 grammes);
- Aquæ, .................. 5viii (250 grammes).

Misce.

Or, a suppository may be ordered.

- Opii pulveris, ................ gr. iss (0.1 gramma);
- Extracti belladonnae foliorum, gr. ¼ (0.01 gramma);
- Olei theobromatis, ... ... . . gr. xlv (3 grammes).

Fiat suppositorium No. 1.

Finally, for vesical spasm, the following prepara-
tion will yield the best results:

- Potassii bromidi, 1 ............ 5iii (10 grammes);
- Aetheris, .................. mxx (0.6 gramma);
- Syrupi, .......................... 5 (30 grammes);
- Aquæ destillatæ, .......... 5iv (120 grammes).

M. Sig.: Three tablespoonsfuls a day not to be exceeded; plenty of water to be taken after each dose.

Treatment of Epistaxis.—Carry, at a recent meeting of the Société des médecins praticiens de Lyon (Journal de médecine de Paris, September 6, 1913) criticized most of the methods of arresting epistaxis described in current textbooks be-
cause of their allowing the formation of a hemato-
toma in the nasal cavities, with subsequent danger of infection and of initiating severe otitis media through the Eustachian tubes. True, it is recom-

ODIA Recommended not to leave tampons in more than twenty-
hours, but this brings in a risk of another kind —their early removal favoring recurrence of the hemorrhage. The essential defect in the methods referred to, is that no attempt is made to arrest the bleeding directly at its point of origin. The pro-
cedure described by the speaker is intended to overcome this objection.

Five tampons of absorbent cotton about one

centimetre thick are prepared and a string at-
tached. They are then dipped into a solution of antipyrine and introduced in succession into the nasal cavity, the first rather deeply, the next two or three between the inferior turbinate and septum, and the last—the fourth or fifth—quite superfi-
cially at the orifice of the nostril, which it closes up. By this plan, sufficient pressure is always exerted by one or another of the tampons at the precise point from which the bleeding has arisen. This point is, as a matter of fact, very constantly situated—unless a tumor is responsible—on the septum, at the junction of its cartilaginous and cutanemembranous portions. Using this pro-
cedure, arrest of bleeding in from five to ten minutes is assured. The tampons are not necessarily to be removed after twenty-four hours. In fact, Carry prefers to allow them to become discharged almost spontaneously, which occurs when they have become sufficiently expanded and lubricated by the local secretion. At least, only slight traction upon the string should alone be required to draw them out, without fear of detaching the clot and causing fresh hemorrhage.

Boiled water alone, to moisten the cotton tam-
poms, may be sufficient; or, some hemostatic sub-
stance other than antipyrine, e. g., epinephrin,
feropyrine, etc.—but not perchloride of iron—
may be employed. Wherever the urgency of the case permits, aseptic cotton only should be used; the usual precautions to avoid infection should be taken.

Treatment of Pruritus.—W. S. Gottheil, in the Therapeutic Gazette for July, 1913, emphasizes the necessity of eliminating, if possible, all factors that bring on the attacks of itching or increase their se-
verity, whether it be the character or amount of clothing worn day or night, the temperature, the effect of air or water in contact with the skin, or the ascertainable effects of alcohol, tobacco, or other habits. Of drugs the author has found phenol in oily solution most useful; this may be employed with the phenol in a concentration as high as twenty-five per cent. over large areas, without fear. Second to phenol in efficacy stand menthol, thymol, and hydrated chloral, which may be used in oil alone, with the phenol, or in alcoholic or watery so-
lutions of various strengths. The x ray has a pow-
erful influence over the itching in some cases, but generally it has failed in the author’s hands.

Pruritus in the aged may be mitigated by oily in-
junctions and the remedies already mentioned; but advanced cases are practically hopeless. Almost the same may be said of bath pruritus, and of that which comes on in, or is aggravated by, cold weather. Bran, starch, saline, and Turkish or Russian baths may be tried; removal to a warmer climate may be necessary to alleviate the patient’s suffer-
ings.

In the most obstinate forms of local pruritus vig-
orous measures must be resorted to. Painting with pure phenol or with a forty grains (2.5 grammes) to the ounce (30 grammes) solution of silver nitrate, the high tension spark from a metallic elec-
trode, the actual cautery, or even surgical meas-
ures, should be employed.

NEW YORK, SATURDAY, NOVEMBER 29, 1873.

AN IMPORTANT ADVANCE IN ANESTHESIA.

If subsequent experience confirms the results observed in the first hundred cases in which anesthesia has been induced by rectal injections of ether and olive oil, Dr. James T. Gwathmey, of New York, is to be congratulated upon having originated one of the most important of recent advances in the field of anesthetics. The reflexes remain active, the brain being less under the influence of the anesthetic than the lower portions of the body, and a pain free period, lasting from one to three hours, follows the return to consciousness. There is complete relaxation, as in rectal anesthesia by gaseous ether, a matter of great importance in abdominal surgery, and a complete absence of nausea, though as a rule the patient vomits from reflex action before regaining consciousness.

Doctor Gwathmey clears out the bowels, injects five grains of chloroform, two drachms of ether, and two drachms of olive oil, and gives hypodermically from an eighth to a sixth of a grain of morphine and one one hundredth of a grain of atropine half an hour before the operation. Then, by gravity, he passes into the rectum, through a small tube, a seventy-five per cent. solution of ether in olive oil, using one ounce of the mixture for each twenty pounds in weight of the patient, and allowing about one minute for the injection of each ounce. Narcosis usually follows promptly within five minutes after the completion of the injection. Should loss of the reflexes or stertor occur, the solution is drawn off from the rectum by means of the tube which remains in situ and the rectum is washed out with cold water and soapsuds. In one case suspended respiration was restored by the use of carbon dioxide.

It is also recommended that a local anesthetic be injected at the site of the operation, as proposed by Dr. George W. Crile, of Cleveland. Occasionally it is necessary to supplement the rectal injection by the inhalation of a few drops of ether or chloroform. With over 100 patients operated upon, covering a wide variety of operations, there have been no deaths reported under anesthesia, though one patient, all of whose organs were found to be diseased, died twenty-four hours after operation. With children a weaker solution, containing from fifty to sixty-five per cent. of ether, is used.

Rectal anesthesia is no novelty but, so far as we are aware, the use of a solution of ether in oil as proposed by Doctor Gwathmey is new. It has the advantage that the full dose can be administered at one time, leaving the anesthetist free from any mechanical duties, so that he can watch the condition of the patient without being distracted. In cases of emergency, where a skilled anesthetist is not available, the surgeon, with the aid of any other physician, or even of a trained nurse, could probably carry on an operation under this method when he might be debarred from the use of an anesthetic applied by other methods.

It must be borne in mind, however, that this new method of using ether is as yet in the experimental stage. Doctor Gwathmey, in a paper read before the Seventeenth International Medical Congress held in London last August, and in another paper read before the New York Society of Anesthetists last week, laid particular stress upon this fact. It will be necessary to have this method tried out in a number of cases before it can receive unqualified endorsement. In fact one case has been observed in which the anesthesia did not follow even after forty minutes, showing that not all patients are equally susceptible. We have reason to hope, however, from the results so far observed that Doctor Gwathmey’s oil-ether method will turn out to be a distinct improvement in the technic of anesthesia.

The paper read by Doctor Gwathmey before the New York Society of Anesthetists will appear complete in the issue of the Journal for December 6th.
NEWER METHODS OF ARRESTING PULMONARY HEMORRHAGE.

Pulmonary hemorrhage has been aptly characterized as the bête noire of the practitioner and, when severe, the most terrifying and depressing symptom to which the tuberculous patient is subject. The prompt use of morphine to quiet the sufferer and to control the cough which favors the hemorrhage, along with amyl nitrite inhalations to lower the blood pressure rapidly, thus depleting the bleeding area, have been our most reliable remedies among the many available. Yet every clinician of experience knows that even these sometimes prove futile and that a fatal outcome is still relatively frequent. What is needed, in addition to the measures described, is an agent which, injected into the blood stream, will promptly lower the blood pressure in the lungs themselves, thus arresting at once the outpour of blood into the bronchial area. It is here that the pharmacological or physiological study of the action of drugs in animals emphasizes its value in the practical field. It has been shown by Wiggers and also by Carnot and Josserand that while adrenaline raises the total blood pressure and is incapable of arresting experimental pulmonary hemorrhage—tending, in fact, through this action on the bloodvessels, to increase it—an extract of the posterior lobe of the pituitary is capable of arresting it. More recently Rist, according to Carnot (Paris médical, November 1, 1913), used it successfully in severe pulmonary hemorrhage due to tuberculosis. He injected one half cubic centimetre of pituitrin, which corresponds to a decigram of the fresh posterior lobe. In ten cases, there was almost immediate arrest of the bleeding. There was recurrence in three cases, but only in the course of the following few days. In one case, however, there occurred extreme pallor, vertigo, and an increase of the hemorrhage of short duration, soon followed by permanent arrest of the flow. While this suggests the possibility of untoward effects, the imminent danger to life imposes the duty of resorting to very active measures, even though some risk is incurred. Bernard and Delille have also obtained good results in hemoptysis by means of intravenous injections of pituitrin.

Another agent which seems to be gaining the confidence of the practitioner is the recently introduced emetine. Besides the results recorded by Plandin and Joltrain (our issues for October 23th, page 833, and November 15th, page 973), Renon, Lesnè, and others have also placed on record cases in which emetine had been found very efficient. It presents the drawback, however, of being still beyond our ken as to its mode of action, a fact which militates against its use along with other agents, to say nothing of the growing tendency to avoid empiricism in therapeutics.

ETIOLOGY OF TYPHOID FEVER.

With the discovery of the typhoid bacillus by Eberth in 1880, the cause of typhoid fever was generally believed to have been found; but the final proof—that is, the fulfillment of Koch's postulate—has never been established so clearly and definitely as one might wish. One inherent difficulty lies in the impossibility of the experimental production of typhoid fever in guineapigs and rabbits; for, when these animals are infected with pure virulent cultures of the typhoid bacillus, the symptoms they present are not at all similar, either clinically or pathologically, to those in man. Within the last few years, however, several laboratory infections following the ingestion of pure cultures have served to add evidence to the etiological specificity of the typhoid bacillus; and the recent work of Metchníkoff and Besredka with chimpanzees has given further support to this assumption. With the discovery of agglutinins and of their specificity, there seemed to be no longer any question concerning the relation of the typhoid bacillus to the disease.

On the other hand, work with the agglutinins and other antibodies has revealed the fact that conditions usually diagnosticated as typhoid fever included infections entirely unrelated to the typhoid bacillus. We have learned, for instance, that an infection caused by either of the paratyphoid bacilli may appear clinically identical with what is now considered, bacteriologically, as true typhoid. Not only have the paratyphoid infections, to say nothing of such diseases as Malta fever, been differentiated, but also many diseases more common may now be eliminated from the category of typhoid fever. Thus, while more accurate and more comprehensive diagnostic methods have definitely limited the scope of the term typhoid fever, the status of the typhoid bacillus has been more firmly established. Nevertheless, the thesis that the typhoid bacillus with its products is the sole cause of the symptom complex called Typhus abdominalis could not long remain undisputed. It is inconceivable that lesions in direct contact with many different kinds of bacteria—as are the ulcerated Peyer's patches—could fail to offer a favorable substratum to some of these bacteria. And if other bacteria do grow here, it is reasonable to assume that their metabolic products modify more or less profoundly the symptoms of the disease. To those who have been interested in the vaccine treatment of typhoid fever, this idea
has been particularly suggestive. In some cases the use of typhoid vaccine is followed by remarkably rapid improvement, while in others, identical treatment is without apparent effect. The question has therefore arisen, may not some of these failures result from the inadequacy of a pure typhoid vaccine to influence the associated bacteria which are no longer of minor importance at the beginning of the treatment? Clinicians as well as bacteriologists will therefore devote to the recent observations of Loris-Melikoff more than passing consideration. This investigator, working in the laboratory of Professor Metchnikoff of the Pasteur Institute in Paris, was attracted to this study of the bacterial flora accompanying the typhoid bacillus in true typhoid fever; he wished to see if there might be some relation between the bacteria of the intestine and the different forms of the disease. He recognizes as the two chief clinical types: 1. The nervous, associated with adynamic and ataxic symptoms; and, 2, the intestinal, with which hemorrhage and intestinal perforation are associated. These two types may exist separately or they may be so associated that neither seems to predominate. Can the typhoid bacillus be the sole cause of such wide variations? This is the question Loris-Melikoff set himself to answer.

Having in mind the destruction of tissue accompanying ulceration in the intestine, he naturally turned to the proteolytic bacteria which are able to cause necrosis, such as Bacillus perfringens, Bacillus sporogenes, and Bacillus adenomatis maligni. These are all sporogenic, anaerobic bacilli, and his study is limited to this class.

For the isolation of these bacilli, the culture fluid which he found most useful was composed of equal parts of bile and bouillon. With this medium he isolated a bacillus which morphologically, biologically and chemically, in certain characters resembles the three bacilli mentioned above; it was differentiated, however, with sufficient clearness to merit a specific name for itself. This organism, which Loris-Melikoff calls Bacillus satellititis, was found exclusively in the stools of patients suffering with typhoid fever. It occurred neither in fifty normal individuals nor in patients affected with various other diseases, even intestinal infections. Nor did he discover Bacillus satellititis in typhoid bacillus carriers; furthermore, he failed to find it in three cases of typhoid fever in children and in one case of typhoid fever probably due to a laboratory infection.

This organism injected intraperitoneally into guineapigs, causes death within about sixteen hours; and at autopsy the animal shows that the intestinal walls are thickened and softened, the mucous membrane is covered with a whitish, serofibrinous layer and the Peyer's patches are swollen and ulcerated. The mesenteric glands, especially of the ileocecal appendix, are visibly swollen. Animals fed with this organism became thin and died, one at the end of eight days, another at the end of twenty days. In both cases the mucous membrane showed lesions similar to those described, including swelling and ulceration of the Peyer's patches. This bacillus is agglutinated by the serum of typhoid patients up to one in 100.

Another interesting organism isolated at the same time was a variety of Bacillus perfringens. Like Bacillus satellititis, it produces indol and phenol, although in not such large amounts, and also causes swelling and hyperemia of Peyer's patches, but not ulceration.

In seeking a source for Bacillus satellititis among known causes of typhoid fever, Loris-Melikoff examined about fifty oysters collected under good conditions, and found Bacillus satellititis in the stomachs of the majority of them; on the other hand, he found neither the typhoid bacillus nor Bacillus coli.

If this work is confirmed it will mean that typhoid fever can no longer be considered an infection due to a single organism, and we may find in the bacteria associated with the typhoid bacillus an explanation of the different types of the disease. It seems noteworthy that this very interesting discovery was made by Loris-Melikoff while studying only the anaerobic, sporogenic bacilli. Is it not more than likely that studies of the nonsporogenic and the aerobic bacteria will reveal microorganisms of equal importance with Bacillus satellititis?

CERTAIN NEGLECTED ASPECTS OF INFANT MORTALITY.

Philip Van Ingen (New York State Journal of Medicine, November, 1913) shows that so far we have been unable to reduce the mortality of infants under one month of age, although the death rate of older infants and of children has been greatly lessened in recent years. This, he believes, to be due to our defective methods of attacking this problem. By the aid of special nurses who undertake the instruction of expectant mothers and the guidance of mothers during the first month of life of their infants, it has been possible to reduce the death rate for infants under one month from about forty per cent, to only about three per cent. This has been carried out on a small scale—1,375 women having thus far been cared for—but it indicates the lines along which we must work if we are to meet with any success in the reduction of the great mortality among very young infants.
DISCUSSION OF OCULAR COMFORT AND ITS RELATION TO GLARE FROM REFLECTING SURFACES.

F. A. Vaughn and Nelson M. Black (Annals of Ophthalmology, October, 1913) present a very interesting discussion on this subject, quoting very largely from literature. One statement that they make is particularly worth reproducing. They say that the present lamentable condition is largely due to a misguided popular demand upon the illuminating engineer, printer, publisher, illustrator, and lithographer for more and more glare and brilliancy of illumination, and more and more highly glazed and gaudy published product—the artistic results of which the populace think they like, but which could not often on mature judgment be called even in good taste. Thus the potency of popular demand for good or for evil may be illustrated, and the effort should now be made to reverse the course of this huge pendulum which has swung so far in the wrong direction. Illumination can now be obtained of almost any intensity, character, and color; paper of suitable characteristics can be procured, and type and illustrations which do not require paper with the abominable, glossy, glaring characteristics that have been demanded, are being produced with the most realistic and artistically beautiful results imaginable.

ALCOHOLISM IN RUSSIA.

To the student of Russian civilization the prevalence of alcoholism will account in a large part for the barbarism, superstitiousness, and a low grade of morality of the masses. Just how early in life the Russian begins to drink vodka (spirits), the following figures taken by Rosinsky Pratech from two Russian newspapers show: In the Government of Saratoff seventy-nine per cent. of the boys and forty-eight per cent. of the girls, ranging in ages from five to ten years, drank either spirits or beer. Of the 1,350 boys and 600 girls questioned, 206 boys and thirty-five girls drank to intoxication. In the Government of Pskoff of 5,101 children investigated, eighty-three per cent. of the boys and sixty-eight per cent. of the girls drank, the ages ranging from six to eight and in some instances from three to four. Of 4,034 children thirty per cent. of the boys and eight per cent. of the girls drank to intoxication. It is recorded in history that when Vladimir the saint was choosing a new religion for the Russian people he rejected Mohammedanism on the ground that it "does not permit drink and a Russ can’t be without it."

Changes of Address.—Dr. Irving Freedman, to 841 Beck Street, the Bronx, New York, N. Y.

The Nobel Prize in Medicine.—Announcement is made that the Nobel prize in medicine has this year been awarded to Dr. Charles Richet, professor of physiology in the University of Paris. One of his most notable accomplishements was the discovery of anaphylaxis, for which he was awarded the prize of Moscow at the Seventeenth International Medical Congress, held in London last August.

Medical Society of the County of New York.—At the hundred and eighth annual meeting of this society, held on Monday evening, November 28, the following officers were elected: President, Dr. T. Passmore Berens; first vice-president, Dr. Howard Lilienthal; second vice-president, Dr. Frederick E. Sonder; secretary, Dr. John A. MacLennan Young; treasurer, Dr. Milton Mabbott; auditor, Dr. Charles H. Richardson.

The Dr. William Pierson Medical Library Association.—At the twelfth annual meeting of this association, held in Orange, N. J., recently, the following officers were elected: President, Dr. John Hammond Bradshaw, of Orange; vice-president, Dr. Levi W. Halsey, of Montclair; secretary, Dr. Leonard H. Smith, of East Orange; librarian, Dr. Palmer A. Potter, of East Orange. Dr. Lewis A. Stimson, of New York, was the guest of honor, and read a paper on Fractures.

Meetings of Medical Societies to Be Held in Philadelphia during the Coming Week.—Monday, December 1st, Academy of Surgery, Philadelphia Clinical Association; Tuesday, December 2d, Medical Examiners' Association, Wills Hospital Ophthalmic Society; Wednesday, December 3d, Physicians' Motor Club, College of Physicians; Thursday, December 4th, Obstetrical Society; Friday, December 5th, Kensington Branch of the County Society, Southeast Branch of the County Society.

Southern Medical Association.—At the seventh annual meeting of this association, held in Lexington, Ky., on November 18th, 19th, and 20th, under the presidency of Dr. Frank A. Jones, of Memphis, Tenn., the following officers were elected: President, Dr. Stuart McGuire, of Richmond, Va.; first vice-president, Dr. J. W. Jersey, of Greenville, S. C.; second vice-president, Dr. F. H. Clarke, of Lexington, Ky.; secretary and treasurer, Dr. Scale Harris, of Mobile, Ala. Next year's meeting will be held in Richmond, Va.

The Tri-State Medical Association.—At the annual meeting of the Tri-State Medical Association of Mississippi, Arkansas, and Tennessee, held at Memphis, Tenn., on November 11th, 12th, and 13th, the following officers were elected: President, Dr. John Darrington, of Yazoo City, Miss.; first vice-president, Dr. William D. McCollip, of Yazoo City; second vice-president, Dr. Daniel, of Tyronez, Ark.; third vice-president, Dr. Hiram B. Everett, of Memphis, Tenn.; secretary, Dr. James L. Andrews, of Memphis; treasurer, Dr. James A. Vaughan, of Memphis. Next year's meeting will be held in Memphis.

American Association for the Study and Prevention of Infant Mortality.—At the fourth annual meeting of this association, held in Washington, D. C., on November 14 to 17, 1913, under the presidency of Dr. L. Emmet Holt, of New York, the following officers were elected: President, Dr. J. Whitehead6, of Baltimore; first vice-president, Dr. M. J. Rosenau, professor of hygiene and preventive medicine at Harvard University; second vice-president, Miss Julia C. Lathrop, of Washington, D. C.; secretary, Dr. Phillip Van Ingen, of New York; executive secretary, Miss Gertrude Knopf, of Baltimore; treasurer, Mr. Austin McLean, of Baltimore.

Woman Physician Wanted in a Hospital in North China.—An experienced woman physician is needed to carry on the work in the Presbyterian Hospital and Dispensary at Tsinanfu, North China. This city, which has a population of about 250,000, is the capital of Shantung Province, and is situated three hundred miles south of Peking. The hospital has been practically closed for the last three years, owing to the ill health of the physician in charge. For further information relating to this and similar positions, address the Secretary, Student Volunteer Movement for Foreign Missions, 600 Lexington Avenue, New York.

Wisconsin Tuberculosis Association.—At the annual meeting of this association, held recently in Milwaukee, Dr. M. P. Ravenel, of Madison, was elected president. Dr. Gustave Windsheim, of Kenosha, was elected vice-president, Dr. Clarence A. Baer, of Milwaukee, recording secretary, and Dr. Hoyt F. Dearholt, of Milwaukee, executive secretary.
Medical Association of the Greater City of New York.

A special meeting of this association, under the direction of the chairman for the Borough of Brooklyn, will be held at the Imperial, 360 Fulton Street, Brooklyn, on Monday evening, December 1st, at 8:30 o'clock. The program will include the following papers: A Report of the Modern Treatment of Chronic Nephritis, by Dr. Rollin Hills; Anterior Poliomyelitis, by Dr. Irving David Steinhardt; Gastrocoloposis, by Dr. Charles Eugene Lack. These papers will be discussed by Dr. Bruce G. Blackmar, Dr. Frank E. Stone, Dr. Walter Truслов, Dr. Jaques Cortelyou Rushmore, Dr. Robert G. Moore, Dr. Russell Fowler, and Dr. Heinrich Stern. Dr. Robert E. Coughlin is the chairman for Brooklyn.

Correlation of the Dispensary Abuse in Philadelphia.—Plans for the formation of a general social service board and for closer cooperation between the hospitals and the charitable institutions of the city are being formulated by a committee of the Philadelphia County Medical Society. The committee was appointed several months ago and it will report to the society in the near future. The fact that the County Medical Society has been at work for months in an effort to avoid overlapping is important. The work was started on November 12th by Dr. Joseph S. Neff, director of the Department of Health and Charities, in an address at the annual meeting of the Hospital Association of Philadelphia. Speaking of the great expense of charitable work in Philadelphia, Doc
dor Neff stated that the budgets of the free medical attention visit dispensaries weekly, and that the charitable organizations of the city cooperate in their work in the congested districts. He believed that efficient service by the hospitals demands cooperation. For this reason it is planned to have each hospital send a representative to a general mass meeting to be held in the near future to discuss the matter.

Army Medical Corps Examinations.—The surgeon general of the army announces that preliminary examinations for the appointment of first lieutenants in the Medical Corps of the United States Army will be held on January 19, 1914, at points to be hereafter designated. Full information concerning these examinations can be procured upon application to the Surgeon General, United States Army, Washington, D. C. The essential requirements to secure an invitation are that the applicant shall be a citizen of the United States, shall be between twenty-two and thirty years of age, a graduate of a medical school legally authorized to confer the degree of doctor of medicine, and shall be of good moral character and habits, and shall have had at least one year’s hospital training as an interne, after graduation. The examinations will be held simultaneously throughout the country and the points where boards can be convened. Due consideration will be given to localities from which applications are received, in order to lessen the traveling expenses of applicants as much as possible. In order to perfect all necessary arrangements for the examinations, appointment letters can be completed in possession of the adjutant general at least three weeks before the date of examination. Early attention is therefore enjoined upon all intending applicants. There are at present twenty-six vacancies in the medical corps of the army.

Personal.—Colonel R. H. Elliot, formerly of Madras, India, and at present of London, will be in New York from December 5th to December 11th. He will operate according to his method for glaucoma during his stay in New York at the New York Eye and Ear Infirmary on Friday afternoon, December 5th, at the Hermann Knapp Memorial Hospital, on Monday afternoon, December 8th, at the Manhattan Eye and Ear Infirmary, Tuesday afternoon, December 9th, and at the graduate Hospital on Wednesday afternoon, December 10th. While in New York Colonel Elliot's address will be 46 West Fifty-third Street.

Dr. Francis B. Hert, of Brooklyn, has been appointed coroner of Queens County.

Dr. H. H. Goddard has been appointed laryngologist to the Jewish Hospital of Philadelphia.

Dr. A. C. Geddes has been appointed professor of anatomy at the McGill University, Montreal, succeeding Dr. Francis J. Shepherd.

Dr. Wilfred T. Grenfell, the missionary physician of Labrador, was the guest of honor at an informal dinner given by the medical department of the University of Pennsylvania on Monday, November 17th.

Pith of Progressive Literature.

MEDIZINISCHE KLINIK.

September 11, 1913.

Röntgen and Cystoscopy Findings in Cases of Enuresis in Adults.—F. Trembrul found in the great majority of enuresis cases in adults disturbances in the tendon reflexes and the presence of the tache cérébrale; disturbances in the sensory apparatus more particularly thermhypesthesia, ther
mesthesis, and hypalgnesia or only a slowing of the perception faculty on the distal ends of the lower extremities in the region of the plantar side of the toes, on the side of the fibula, and also on the feet and calves. Furthermore, there is found with the aid of the Röntgen rays, a spina bífida occulta and cystoscopically, trabeculae in the bladder. The etiological factor in these cases seems to be some anatomical defect in the lowest portion of the spinal cord, a so called myelodysplasia.

Reappearance of Scarlet Fever.—Lämmert has from thirty to fifty scarlet fever cases a year, and in the last ten years has found a recurrence of scarlet fever in three cases. In one of these the second attack was by no means milder but led to exitus letalis in a few days with the severest symp
toms.

September 21, 1913.

The Wassermann Reaction in Tabes.—E. Redlich asserts that while in progressive paralysis almost all cases show the positive Wassermann reaction, there is in tabes a considerable proportion whose reactions are negative. These are usually the ones who in the past few years have had mercury or salvarsan treatment. In progressive par
alys the Wassermann reaction is much more res
tistant and cannot often be influenced by specific treatment. The absence of the Wassermann re
caction should not be taken as a criterion for the prog
osis or antiluetic treatment of tabes even though according to the experiences of the author, the majority of the negative cases or those becom
ing negative during treatment show a benign sta
tionary character. It would be of greatest prac
tical interest to decide whether, and how many of, the negative reacting cases of syphilis later become subject to tabes or progressive paralysis.

Body Temperatures in the Aged.—H. Schles
inger says that in the aged, the normal body tem
erature is not reduced but rather a little higher. Because of the poorer circulation in the skin the axillary temperatures are incorrect and misleading. Therefore the temperature of old people should be taken only in the rectum. The weaker and more asthenic a person is, the greater the differences be
tween the axillary and rectal temperatures up to +7 °C. For this reason heterothermias are to be used with reserve in forming the diagnoses of local disease in the aged.

September 26, 1913.

Mortality of Sick Infants during the First Few Days of Their Stay in the Hospital.—H. Putzig says that the mortalities from acute metabolic dis
turbances of 33.8 per cent., from pneumonias of 20.5 per cent., and from chronic metabolic distur
bances of 16.2 per cent., form the largest contingent
of all the mortalities of those children dying a few days after their admission to the children's hospitals. The greatest danger seems to threaten the infants in the first four months of their lives. These children when admitted are usually emaciated in the highest degree. Almost one third of these children have a subnormal temperature upon admission. Furthermore, premature births, twins, the last children of very large families, and the children of tuberculous parents are very much handicapped. The value of natural feeding is again proved from these statistics. Therefore doctors, midwives, etc., should insist upon the feeding of these children with mother's milk for the longest possible periods.

The Treatment of Eclampsia.—F. Engelmann shows that the results of eclampsia treatment in the gynecological clinic at Dortmund have improved since the former methods of inducing premature delivery have been discontinued. There have been only four deaths in the last seventy-five cases. The therapy advocated by this author lies midway between extreme conservative treatment and its opposite. 1. Isolation of the patient. 2. Withdrawal of all stimuli. 3. Performance of all manipulations under chloroform. 4. Chloral regularly administered by enema. 5. The induction of labor by rupture of the membranes or mechanical dilatation of the cervix. 6. Artificial delivery as soon as this is possible without much danger.

Morphinism and Cocainism.—A. Friedländer gives a comprehensive summary of the symptomatology and therapy of morphinism and cocainism. In reference to the therapy in poisoning by these two alkaloids, the author advocates the point of view of the rapid withdrawal and warns against attempts to substitute another alkaloid for the morphine. In the rapid cure, lasting about ten days, the addition of scopolamine to morphine is recommended, because then it is possible from the very beginning to get along with smaller doses of morphine. The withdrawal cure is always successful when the patient adheres to the treatment faithfully. The important thing is to prevent a relapse. Only when the personality of the patient has been improved, when his will power has been strengthened, and when he has been made strong and free from within, can the task be considered as solved. Months and years are necessary for this psychic influence and control. This makes the radical treatment of morphinism at the present time hopeful. The prognosis in cocainism is on the whole better than in morphinism.

PARIS MÉDICAL.
October 25, 1913.

Formaldehyde Disinfection.—G. H. Lemoine states that the simplest and least costly method of disinfecting rooms is to heat, for each cubic metre of space, twelve c. c. of a fluid consisting of five parts of commercial forty per cent. formaldehyde solution and one part of water. One receptacle should be provided for every eighty cubic metres of space in the room or hall to be disinfected. The receptacles are placed on tripods, the latter resting on sand in rooms with wooden flooring, and are heated with alcohol lamps until the solution has completely evaporated. Recent experimentation has shown that infected clothing can be sterilized through and through by using thirty-six c. c. of the formaldehyde solution for every cubic metre of space, by bringing the air surrounding the sterilizer to a temperature of at least ninety degrees C. within an hour, and keeping this air moist with steam during the entire process of disinfection—four hours at least. Clothing can thus be disinfected without losing its shape or color. Mattresses can be disinfected throughout if the seams be opened on one side and the contents separated into two or three layers, though such sterilization is not generally required, mattresses usually being soiled only superficially. The process described does not tarnish metal articles.

Larval Malaria.—C. L. Urriola points out that there are cases of malaria in which the sole clinical manifestation is some symptom not ordinarily considered characteristic of the disease, together with a very moderate degree of intermittent or continuous fever and the constant presence of black, blue, as well as sometimes of ochre pigment in the blood and urine. This larval type of malaria does not follow ordinary acute paroxysms, but appears ab initio. No plasmodia are to be seen in the blood at the time. Among the various forms it may assume, the following have been carefully studied by the author and found related to the appearance of the pigment in the urine: (1) Sensation of cold in the lower limbs and back; (2) edema of the extremities or face; (3) trigeminal or intercostal neuralgia; (4) peripheral neuritis with paraplegia of the flexor variety; (5) attacks of dizziness, and (6) pain in the epigastrium, with or without periodic vomiting or enlargement and tenderness of the spleen and liver. With each of these manifestations may be combined anemia, anorexia, malaise, sweating, and slight fever, all showing a tendency to periodicity. The black pigment is always abundant in the urine and is easily seen microscopically, provided the slide be moved around to set the pigment particles in motion. The blue particles are equally pathognomonic, but are much fewer in number and usually smaller than the black. Ten cases illustrating the various forms of larval malaria are reported. Recovery always followed the use of a chologogue—not specified—or small doses of quinine for a few weeks. Urriola holds that many cases of so called beriberi in Panama, whence he writes, represent in reality the neuritic form of larval malaria. Similar neuritis may be caused by the presence of Ankylostoma duodenale and Trichocephalus dispar.

PRESSE MÉDICALE.
October 25, 1913.

Latent Spina Bifida with Lumbar Tumor.—A. Broca reports the case of a child suffering from partial paralysis of the lower extremities, cold and cyanotic feet, recurrent chilblains, luxation of the distal joint of the right great toe, and slightly incurved tibias. Sensation was practically normal, the cerebral functions unimpaired, and hydrocephalus absent. Examination of the lumbar spine revealed an enlargement the size of half an orange, extending from the level of the second lumbar to
the first sacral vertebra, of pasty consistence, painless, irreducible, with volume unmodified by respiration or physical exertion, and in part covered with long, fine hairs. Both the tumor and paresis had been noticed at birth. Local palpation and x-ray examination showed absence of the third, fourth, and fifth lumbar spinous processes, with malformation of the upper two lumbar spines. The absence of fluctuation and umbilication suggested the presence merely of a latent spina bifida with rather large connective tissue deposit between the cord and skin, rather than a myelomingingocele, and operation was therefore deemed useless, the innervation of the lower limbs being compromised solely through irremediable congenital malformation of the cord itself. Operation would be indicated only in the event of a later growth of the tumor, causing additional symptoms due to pressure on the cord.

REVUE DE MÉDECINE.
October, 1913.

Diabetes with Hepatic Cirrhosis.—Bouchut and Volmat report two cases of hypertrophic cirrhosis of the liver in which all the cardinal symptoms of diabetes mellitus were present. In one case ascites and icterus existed, but not in the other. The second case also showed lung tuberculosis. Restriction of carbohydrates relieved the diabetic symptoms considerably in each instance. The authors discuss so called hepatic diabetes in general, but offer no new theory or conclusion.

The Liver in Chronic Malaria.—C. Fraga, summarizing the results of a clinical study on the subject, asserts that chronic malaria does not cause profound hepatic disturbances; the disorders produced are changeable, generally mild, and overcome by ordinary therapeutic measures. Physical examination may show merely enlargement of the liver, at times with tenderness of the left lobe; generally, indeed, there is no change either in volume, shape, consistency, or sensibility to pressure. Functional tests, including urea estimation, urobilin reaction, experimental ammoniauria, alimentary glycosuria and lipemia, and the administration of methylene blue, confirmed the conclusion suggested by physical examination. Fraga maintains that any pronounced hepatic disorder observed in chronic malaria is due to other causes than the infection itself, especially alcoholism and poor food.

ROUSSKY VRATCH.
August 10, 1913.

Cholesterinemia.—R. M. Obakevitch investigated the presence of cholesterin in the blood in health and in various affections. He concludes that the normal cholesterin in the blood varies from 1.4 to 1.8 grammes in one litre of serum. When food rich in cholesterin is ingested (milk, cream, butter, the yolk of eggs, brain), the cholesterin in the blood is greatly increased (digestive cholesterinemia); on the other hand, a diet poor in cholesterin gives a diminution of cholesterin in the blood. Hypercholesterinemia is observed in pregnancy, nephritis, gallstones, obstructive jaundice, arteriosclerosis, syphilis, and convalescence from infectious diseases. Hypcholesterinemia is observed, as a rule, in acute and subacute infections during the height of the fever, in acute anemia and hematogenous jaundice. Normal cholesterinemia is observed in gastric catarrh and chronic diseases not accompanied by elevation of temperature. In hypercholesterinemia, food rich in cholesterin is contraindicated.

Experimental Measles.—A. U. Urgelunas attempted to infect a number of monkeys with measles, using different methods of transmitting the disease from affected children. The results proved negative, although in one case a fatal illness developed in the monkey, somewhat resembling measles.

August 17, 1913.

Experiments in Cultivating Plasmodium vivax According to Bass’s Method.—P. I. Pitchugin successfully cultivated Plasmodium vivax by the use of the method first suggested by Bass. He obtained two generations of the parasite, showing complete cycles of development. In the third generation only merozoites and schizonts were observed.

The Treatment of Typhus with Iodine.—V. Utuzhaninoff observed a marked beneficial effect from the administration of iodine in typhus. The fever rapidly subsided, the eruption became less marked, delirium disappeared, and the mortality was practically nil. The drug was administered either in milk or in the following mixture:

R. Emulsionis seminis cannabis sativae, 5xii (360g); Muelaginis gummi acaecae, 5x (400); Tinctura iod. 5x (500); Tinctura menthe piperitae, 5x (20). Misse. Sig.: Four tablespoonfuls daily.

The author attributes the action of iodine to hyperleucocytosis.

LANCET.
November 8, 1913.

Report on Typhoid Carriers.—D. S. Davies and I. Walker Hall have made frequent observations on a woman of thirty-three years of age who had an attack of typhoid fever in 1905, and who remained a carrier from that time until about two years ago. Since her recovery from typhoid she has been known to have been the source of infection of eight others. It was first discovered in 1909 that she was a carrier, the organisms being found in her urine. At that time hexamethylenamine was given continuously for a period of three months. It caused a decrease in the number of typhoid organisms in her urine, but did not entirely remove them. As the result of repeated doses of an autogenous typhoid vaccine, in doses up to 1,000 million organisms, given for a period of five months, the bacilli disappeared from her urine for about four months. They reappeared, however, though her blood agglutinated the typhoid bacillus in dilutions varying from one to 1,000 to one to 1,800. In response to a three weeks’ course of potassium citrate the organisms again disappeared from her urine for several months. Late in 1910, a cystoscopie examination showed inflammation about her right ureteric orifice, and urine from this side contained bacilli, while that from the left ureter was free from them. X ray examination showed a shadow in the right renal region. Operation on the
right kidney disclosed ten small calculi in the pelvis. No abscess was found. The calculi were removed, and a good recovery was made from the operation. The operation, however, was followed by a fever for a few days, during which time typhoid bacilli were isolated from her blood, though the agglutinating power of her serum was then as high as 1,500. The fluid and the calculi found in the pelvis of the kidney gave pure cultures of typhoid bacilli, and these were also present in her urine a few days after the operation, and almost constantly thereafter for about eight months. Two thorough courses of hexamethylenetetramin triborate did not alter the excretion of the bacilli. In July, 1911, a bacterial emulsion was prepared from her own bacilli and administered to the patient, and in October of the same year typhoid bacilli appeared in her urine for the last time. At present she remains free from typhoid bacilluria, and the orifice of her right ureter is completely normal again.

Sensitized Virus Vaccination in Gonorrhea and Its Complications.—Using vaccines of killed gonococci, Besredka, Louis Cruveilhier had obtained strikingly good results in the treatment of most of the complications of gonorrhea. Acute epididymitis responded promptly, becoming painless in from twelve to forty-eight hours, along with an equally rapid subsidence of all of the local signs of inflammation. Only two or three injections were required, and they were given at intervals of forty-eight hours. No relapses have been reported. Acute and chronic gonorrheal involvements of the uterus and annexa have shown equally brilliant results in most cases, as have also cases of acute and chronic gonorrheal arthritis. Both acute and chronic urethritis have shown very favorable and extremely rapid response to the treatment. In a few very refractory cases of gonorrheal infection, it has been found necessary to use living sensitized virus, which has usually been productive of prompt benefit or even of cure. In none of the patients was there any severe reaction to the injections.

Researches on the Pathogenesis of Cancer.—De Keating-Hart says that the parasitic theory is given up, not as being impossible, but because, according to the present state of knowledge, it is unlikely and irrational. In microbial diseases the injured cell leaves the virus intact, and one would therefore have to imagine a parasitism contrary to the histological laws of higher organisms. The absolute similarity of the conditions which govern the grafting of normal and of cancerous cells is recognized, and determine failure or success. It has been shown that ectopy, and the metastatic capability of cancerous cells, are the consequences of their acquired properties and of their cellular construction. The purely hypothetical and inadequate interpretations of the greater number of authors are put aside. The irritative theory is accepted as being the only one which embraces all the known facts in cancerous etiology. The biological conditions created by irritation in the cells submitted to it have been studied. The reproductive power of cancerous cells has been proved, and their nutritive requirements demonstrated. From these facts he infers that cancer is produced by cells overcultivated for a long time in the irritated zones of the organism.

Premature Loss of Hair and Hygiene of the Scalp.—Douglas Freshwater speaks of the various forms of baldness: First, alopecia senilis, then alopecia prematura, which he subdivides into two varieties, the idiopathic and the symptomatic. Causes suggested for the idiopathic variety are the wearing of hard hats, the wearing of tight collars, shallow breathing, the wetting of the head with water, indoor occupations, and derangements of the digestive and genital tracts. Women suffer much less than men from this form of baldness, perhaps because they give more attention to the brushing and dressing of the hair, or because the connective tissue bundles in the scalp are larger than in men, or because they do not wear tight fitting hats of impermeable material, or because they seldom wet the head. Symptomatic baldness may be due to three seborrhoeic conditions: Acute fevers, syphilis, and infection of the hair follicles in certain skin diseases, alopecia follicularis. He gives considerable attention to the seborrhoeic conditions. Regarding local treatment, he considers it of paramount importance, and the first part is the same for all forms of seborrhoea. It is necessary first of all to remove from the scalp the scurf or any greasy scales that may be present, as they tend to block the mouths of the hair follicles and provide a favorable soil for bacterial growth. During the first month of treatment the head should be frequently washed and anointed daily with an antiseptic ointment. The head should be shampooed every evening with a spirit soap lotion and then, after the hair has been thoroughly dried, the following ointment is rubbed carefully into the entire surface of the scalp.

2 Acidi salicylici, .......... gr. x (0.65 grammae);
Sulphuris praecipitat., .......... gr. xxx (2 grammes);
Olej rose, ............... nji (0.13 grammes);
Adips benzoatis, .......... 3j (30 grammes).

Misc. Ft. unguentum.

Drugs that should never be used when the hair is light or gray are: Roserinc, naphthol, empyroform, oil of cade, ichthyl, thiol, and tannic acid. Massage is very valuable as an adjunct; at least twenty minutes a day should be devoted to it. In advanced cases of baldness stimulation with a faradic brush and the high frequency current may be added. Light and air are highly beneficial to the growth of hair. Considerable space is given to the hygiene of the hair, teaching children to brush and comb it properly, and the use of a shampoo.

Clinical Aspects of the Regeneration of Bone, as Manifested by a Study of the Union of Fractures.—E. Stanley Ryerson has studied this subject from the x-ray plates of fractures in which union was taking place. He has found that the first parts of the area in relation to the fracture to show evidence of new bone formation are the medullary cavity and the surface of the bones in relation to
the line of fracture. The ensheathing callus begins to show close to the bone, and gradually extends out until it reaches the periosteum. If the periosteum is intact, the outer limit of the callus is definitely marked off by it from the muscular and subcutaneous tissues, whereas if the periosteum is torn, the callus extends irregularly out into the soft tissues. The last part of the space about the fractured ends of the bones which becomes obscured by the shadow indicating new bone formation, is the osteoperiosteal angle. In some cases this part of the space has remained clear for weeks or even months after the occurrence of the fracture. He argues from this that if the periosteum was osteogenetic, new bone would be produced by it over the area where it is stripped up from the bone, and the osteoperiosteal angle would be one of the first parts to be filled up, which is not the case. The natural inference from that is that the periosteum is not osteogenetic in character.

An Epidemic of Jaundice.—Malcolm Mackay describes a local epidemic of jaundice and concludes from his observations that the disease is infectious, possibly contagious; that gastroenteritis is present; and that the jaundice is of the obstructive type characteristic of the catarhal form.

BOSTON MEDICAL AND SURGICAL JOURNAL.
November 13, 1913.

A Case of Orthostatic Albuminuria Treated by Exercise.—Henry J. Fitzsimmons reports the case of a child apparently normal, except that when she stood erect her kidneys excreted albumin. From the observations made upon children with chronic constipation, where the condition was cured by exercise, the writer had noticed that decrease in the lumbar lordosis was coincident with a lessening of the complaint. Exercises were therefore commenced and carried on vigorously. All muscular exertion which tended to lessen the lumbar lordosis was encouraged, while all positions which increased it were forbidden. These exercises were definitely arranged, first to increase the muscle power of the abdominal walls. Particular attention was paid to the recti, superior and inferior obliques, and the transversals. These exercises for muscle power were carried on simultaneously with instructions in “muscle control.” Muscle control, the writer feels, is very important, since by this means the patient has not only the power to hold a given position, but assumes this position first consciously during the training of certain muscles, then unconsciously. From this unconscious assumption of this position she passes into a condition in which she assumes a proper attitude, not occasionally, but continuously. This condition was obtained by insisting during all the exercises on a concentration upon the exercises and the absolute exclusion of all other thoughts or actions. At first there was some difficulty in doing this, but as the patient was unusually intelligent, an explanation of the importance of doing what was desired in the right way soon gave the result desired. The urine was examined once a week for three weeks. The first examination showed a normal urine except for a slight trace of albumin; the second week there was the slightest possible trace of albumin; the third week the urine was normal in every respect. Then for six months the urine was examined occasionally, but no trace of albumin was found. The child now stands properly.

Acute Acid Intoxication in Children, by T. C. McClave.—See this JOURNAL for July 5th, p. 40.

The Need of Whole Time Health Officers.—The modern whole time health officer, says H. B. Wood, is not simply a registrar of statistics, a placard of houses, or a public prosecutor. He is a compiler of statistics, a public instructor, a true sanitarian. His office should be a bureau of information, to collect and to disperse knowledge. He should not alone formulate, but also execute, plans for saving human life. The improvement of industrial, social, scholastic, and vital conditions is his work. With the perfection of State wide organizations of whole time health officers and the formation of the much needed national department of health, a cooperative system will be developed, with relationships similar to, but with affiliations closer than, the State militia with the federal army.

Osteochondrosis dissecans.—John Ridlon reports three cases of this condition, one so rare that many authorities do not take it into account when considering the diagnosis of knee joint trouble. Of the cases which have been reported, few have been presented with röntgenograms, and without these he cannot well understand how a certain diagnosis can be made prior to operation. He does not believe that our present knowledge of this condition warrants us in discussing its relations to other loose and partially detached bodies in the knee joint or in its possible relation to osteoarthritis.

Results of Bone Plastic and Graft Operations on the Spine for the Cure of Pott's Disease.—J. J. Nutt presents the report of fifteen cases, with the following conclusions: 1. While he does not unqualifiedly condemn the operation on account of the poor results in some of the cases, he does not believe that the claims which have been made for it have been substantiated. 2. If alterations in technique, such as the implantation of a longer graft and the extension of the period of postoperative use of external support, are to improve the results, reports should be forthcoming two years after the operation, and not before. 3. The danger in the use of the operation does not lie in the operation itself, but in the creation of a sense of false security, a feeling that a cure of a chronic disease has been produced, and a consequent neglect of other therapeutic measures.

Charcot Joints as an Initial or Early Symptom in Tabes dorsalis.—H. L. Taylor reaches the following conclusions: 1. Charcot joints and spontaneous fractures are often initial or early signs. 2. They often precede the ataxic gait, and are of diagnostic importance in calling attention to the underlying tabes. 3. Charcot joints are frequently of traumatic origin and often follow fractures and lesser injuries. 4. The results of orthopedic treatment in early or moderately advanced cases of Charcot joint are extremely satisfactory. 5. Orthopedic treatment by protective splinting should...
also be used in the loose joints of tabes due to hypotonus before the appearance of swelling and effusion. As ataxia is often one of the later symptoms to appear; the term "laborum ataxia" to designate the affection is misleading, and should be discarded.

The Recognition of Early Changes in the Larynx in Tuberculosis.—W. E. Casselberry considers that hyperplasia of a mammillated or other typical aspect, commencing at or near the subglottic portion of the base of the vocal process and gradually marked by a furrow in the vocal angle, is not only one of the earliest but also the most distinctive of all the initial changes caused by tuberculosis in the larynx.

The Significance of Gastric Ulcer with Respect to Gastric Cancer.—F. Smithers has made a study of 566 consecutive cases of gastric cancer, operatively and pathologically demonstrated, in an attempt to determine how frequently chronic ulcer precedes cancer, and how this change is manifested clinically. He finds that a number of cases clinically admitting only a diagnosis of chronic gastric ulcer are shown to be malignant at operation and that many cases of gastric cancer reveal a precancerous history which at any stage prior to the terminal period of malignancy satisfies the clinical symptom complex of chronic gastric ulcer.

An Etiological Study of Hodgkin's Disease.—C. H. Bunting and J. L. Yates in a recent publication described a diphtheroid organism obtained in pure culture in four cases of this disease and observed in three others. In order to determine the possibility of an etiological relationship between this organism and the disease, they have employed the Macacus rhesus monkey for inoculation experiments, and report that on account of the similarity of the picture in the lymph nodes to that in the early stage of Hodgkin's disease in the human being and of the blood picture, showing the changes seen in human patients with the disease, they feel more assured of the etiological relationship of the organism (which they have designated Corynebacterium hodgkinii) to the disease.

MEDICAL RECORD
November 15, 1913.

Cases of Tumor of the Lungs and Mediastinum Simulating Pulmonary Tuberculosis.—W. H. Swan states that several cases of intrathoracic tumor which had been mistaken for tuberculosis have come under his observation. In six cases of this kind which he relates, the real conditions were respectively, lymphosarcoma of the mediastinum, primary carcinoma of the lung, persistent thymus (possibly Hodgkin's disease), malignant disease of lungs (two cases), and small round celled sarcoma of first rib, including lung and pleura. After commenting on the symptomatology and diagnosis, he concludes that: 1. Intrathoracic tumors are probably more frequent than has been supposed; 2, they are occasionally coexistent with tuberculosis; 3, early in their course they are likely to suggest tuberculosis, and differentiation may be impossible; 4, in cases of doubt it is very important that all hygienic measures for the treatment of tuberculosis be instituted at once, pending a definite diagnosis.

Pruritus ani pertinax.—W. P. Cunningham says that much is expected from the discovery and cure of fissures or hemorrhoids, but fissures are often the result and not the cause of the patient's scratching. There are many cases of pruritus ani where neither fissures nor hemorrhoids exist. After referring to other possible etiological factors, he states that if the obscurity of the causation cannot be cleared away, a tentative diagnosis of portal obstruction will serve as a reasonable basis of internal treatment. Occasionally, topical applications alleviate temporarily. The x ray is credited by some with gratifying results. Very frequently we are forced to the use of narcotics to enable the patient to sleep. For this purpose cannabis indica, gelsemium, or belladonna, with or without morphine, in the form of a suppository, may be employed. Some surgeons offer to operate in exaggerated cases, but there is a lack of unanimity as to the wisdom of the procedures. The "eczema" which almost invariably complicates pruritus ani must be treated on general principles, and soothing applications are usually called for.

Transplantation of Bone for Flail Joint Produced by Inflammatory Destruction of Joint.—A. O. Wilensky reports this case. Under local anesthesia, by the injection of a two per cent. solution of alcohol, an incision was made at the side of the injured finger from the tip to near the second joint, and deepened through the periosteum; the latter being lifted away from the bones. Scar tissue between the ends was dissected out, the ends of the bones freshened, and the cortex removed from the side of the distal phalanx, leaving a fresh area of cancellous bone. The second phalanx was then split longitudinally from a little below the second joint, and the fragment slid down so that it overlapped the first and second phalanges. No sutures were thought necessary to hold the transplant in place. The wound was closed without drainage. The primary wound occurred. At the end of three weeks there was solid bony union, and at the end of four months the patient had a perfectly useful finger.

A Diphtheria Carrier Treated with Culture of Staphylococcus pyogenes aureus.—I. E. Bischoff again demonstrates the apparent specificity of the culture in question in cases resistant to the ordinary means. On July 14th the patient sprayed his throat every four hours with a twelve hour bouillon culture of Staphylococcus pyogenes aureus. July 15th another fresh twelve hour culture was used, and from July 16th to 20th a normal saline suspension of the microorganism. On July 20th the first negative throat culture was obtained, and since then the cultures have remained negative. The mild pharyngitis produced by the culture spray quickly subsided under a Dobell's solution spray.

A New Colostomy Apparatus.—H. B. Delatour in 1907 devised a double cup apparatus, which acted very well until there was an excessive fluid discharge, when there might be some leakage. In fitting the apparatus to subsequent cases it was found necessary to change the shape of the cup, and provide it with an opening to which could be attached a rubber receptacle for the collection of
excessive discharges. The improved cup is so shaped that it fits well beneath the clothing without being noticeable, and the rim face of the cup, which approximates the tissue surrounding the fissure, has a depression or groove into which the skin will project upon very slight pressure, thus forming practically an airtight support.

AMERICAN JOURNAL OF THE MEDICAL SCIENCES.
October, 1913.

The Influence of Skeletal Defects, Congenital and Acquired, upon the Body in Health and Disease.—C. F. Painter reviews a large number of skeletal anomalies, and their effects upon the individual, to which attention has been called of late, and goes on to say that in childhood and youth such general processes as growth may well be influenced by the train of functional disturbances set in operation by a skeletal anomaly; and this may apply to mental development as well as physical. The problems presented comprise much of the work which those who are becoming interested in chronic medicine have laid out for themselves. A new and attractive field for investigation exists. The need for a correlation of the knowledge which has been accumulated through the activities of workers in various special lines of research is becoming more and more evident. We are getting past the period when, within the narrow limits of our particular spheres of activity, we can assume a position of authority and say that this or that ailment can be properly treated only by this or that specialist. It can be properly treated only by the one who has the best conception of the anatomophysiological relations of the condition before him, and is broad enough to act upon that knowledge. A better conception of the functional anatomical relations of the human being, not merely the ability to recognize and call by name its structural components, is what is needed in medicine and surgery.

The Value of X Ray Examinations in the Diagnosis of Ulcer of the Stomach and Duodenum.—J. Friedenwald and F. H. Baetjer present twenty cases of peptic ulcer, ten gastric and ten duodenal, and state that from their studies of these, together with their experience with many others, they are justified in drawing the following conclusions: 1. The x ray offers most valuable assistance as an aid in the diagnosis of peptic ulcer, though this method is not yet sufficiently exact to be relied upon alone. 2. In duodenal ulcer there is an excessive motility of the stomach, with such rapid evacuation that the greater portion of its contents is emptied within the first half hour. There is supersensitivity of the duodenum, with formation, usually, of a vacant area, which remains fixed in all the examination. 3. The diagnosis of gastric ulcer can be made only in certain situations: when the lesion is on the anterior surface of the stomach and along the anterior surface of the lesser and greater curvature. In gastric ulcer, whatever its location, we can always look for retention of contents. In certain instances there is a vacant area in the pylorus; frequently there is a tendency to hourglass contraction. 4. The x ray affords an almost absolute means of differentiating between gastric and duodenal ulcer. 5. By means of the x ray we can positively rule out the presence of duodenal ulcer. 6. We can approximately determine the healing of an ulcer, which cannot be as certainly determined in any other way.

The Present Situation in Syphilis.—W. A. Pusey enumerates the great additions which have been made to the management of syphilis in the last ten years as follows: Diagnosis by demonstration of theSpirochaeta pallida; diagnosis by the Wassermann reaction; the use of the Wassermann reaction as a criterion of the effect of treatment; diagnosis by Noguchi’s cutaneous reaction; prophylaxis by inoculation of thirty-three per cent. calomel ointment shortly after infection; treatment by salvarsan and its derivatives. He presents the following conclusions regarding salvarsan: 1. Salvarsan has real dangers; they are remote, but, when they occur, serious. 2. As far as can be deduced from our present knowledge, there is no reason to believe that it will lessen the occurrence of parasyphilitic nervous affections, and some ground for fear that it may predispose to them, except in those cases in which it cures the disease. 3. It is a powerful symptomatic remedy. 4. In cases in which vigorous treatment is begun before the generalization of the disease there is strong ground for believing that syphilis can be aborted. This possibly applies to a few early cases with secondaries. 5. In all other cases in the secondary period its “curative” use may do more harm than good.

Syphilis in the Etiology of Fibrous Osteitis.—P. G. Skillern, Jr., finds from his study of the affection that, 1. fibrous osteitis, in some cases at least, is identical with late hereditary syphilis of bone; 2. the connection of syphilis with this and other bone diseases of obscure etiology should be thoroughly worked out with the aid now afforded by the Wassermann reaction; 3. this disease is curable by conservative measures, and may be struck off from the fast diminishing list of bone diseases calling for amputation.

AMERICAN JOURNAL OF OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN.
October, 1913.

Arterial Ligation, with Lymphatic Block, in the Treatment of Advanced Cancer of the Pelvic Organs. A Report of Fifty-Six Cases.—Bainbridge calls attention to the serious problem in the treatment of malignant disease that is presented to the surgeon in the management of those cases of cancer of the pelvic organs which are commonly placed in the category of the “inoperable, irremovable, and incurable.” He first points out that in many cases enlarged lymph nodes are of a purely hyperplastic character, and not cancerous. Lymphatic dissemination through attempts at removal of such nodes is not a deterrent factor, and such patients should not be denied the possibility of relief by operation. Furthermore, by lessening the blood supply to the cancerous tissue, and by blocking the avenues of lymphatic absorption, the progress of the disease may be retarded, pressure and other symptoms mitigated, and the danger of death from hemorrhage removed, where removal of the cancerous mass is impossible. The essential purposes of the author’s method are to diminish the
blood supply to the area of cancerous involvement by ligating the chief vessel and to shut off the avenues of absorption of cancer cells and toxic material, this latter end being accomplished by removing the lymphatic nodes and vessels from the receptaculum chyli to the obturator foramen on both sides. The paper also includes a discussion of the indications for this form of treatment and a description of the technic of the operation.

Prolonged Amenorrhea with Bilateral Ovarian Dermoid Cysts.—Wiener reports a case of a woman of twenty-five years who had not menstruated for five. At operation bilateral dermoids were present. On reviewing the literature the author found that little attention had been paid to the possibility of amenorrhea being due to ovarian tumors. According to one investigator, amenorrhea does occur in about two to three per cent. of ovarian tumors.

The Treatment of Anteflexion, Defective Function, and Sterility by Glass or Silver Stems.—Dickinson and Smith present in considerable detail the use of the stem in the treatment of the foregoing conditions. They feel that when it is applied to properly selected patients it gives much more satisfactory results than any of the other methods.

AMERICAN JOURNAL OF ORTHOPEDIC SURGERY.

July, 1913.

An Introduction to the Symposium on Lateral Curvature.—Ansel G. Cook, in a consideration of scoliosis from a standpoint of balance, considers that the key to the whole situation is the lumbar spine, that the lumbar spine is the centre of motion of the human body, and that anything that affects the balance of the human body affects the curve of the lumbar spine. The object of the mechanical treatment, therefore, should be the reversal of the lumbar curve, regardless of other curves, and the elimination of everything that prevents the reversal of this curve. "If you can once reverse the lumbar curve and hold it, you may count your cure."

"Rotations of the spine on its own axis, tiltings of the pelvis, high or low shoulders, will regulate themselves and require no special attention." A fenestrated corset is described which acts directly on the lumbar curve.

 Movements or Positions of the Normal Spine and Their Relations to Lateral Curvature.—E. S. Abbott gives the results of a thorough study of all of the movements and positions of the normal spine, illustrated by tracings and drawings taken from x rays. This article can best be appreciated by reading it.

Corrective Jackets in the Treatment of Structural Scoliosis, with Especial Reference to Measurement and Record.—This contribution, by Albert H. Fricberg, is an expression of his personal experience with the Abbott method of treating structural scoliosis. It embodies his opinion of the method, and contains a complete report of five cases thus treated. The author's method of making graphic records of the lateral deviation is described.

Scoliosis; Its Prognosis.—John L. Porter says that there are so many factors to be weighed and considered in estimating the prognosis in scoliosis that in many cases it is difficult to make any very definite statement as to the probable result of treatment. The author discusses the prognosis from all of its many phases and makes the following statement: "I now limit my prognosis to stating what I hope may be accomplished by treatment, telling the patient frankly that improvement is the rule, and that in a certain percentage of cases cures are possible, but that I cannot tell beforehand whether a cure or only improvement is possible."

A Consideration of the Correction of the Fixed Types of Lateral Curvature, Complicated by Visceral Derangements, Especially Those of the Cardiac Variety, with a Slight Modification of Abbott's Method.—R. O. Meisenbach discusses the various visceral changes that occur in scoliosis and the far reaching benefits derived from treatment. His conclusions are as follows: 1. That it is surprising to see how small a change of blood pressure takes place when the rotary force and flexion are applied. 2. That cases troubled by ptosis and gastric symptoms may improve in general health with a disappearance of symptoms after the spine has been corrected. 3. That the hemoglobin may often increase its percentage after the spine has been corrected, and without medication. 4. That it should not be the rule to attempt to build patients up by medication, and thereby lose time in spinal correction, but that after the spine is corrected these measures may be undertaken with better success. 5. Cardiac lesions, especially functional, due to pressure, may improve after correction, and are not increased. 6. In cases of the severest types, with great deformity of spine and derangement of viscera, treatment should be undertaken cautiously, with a view of improving the general condition of the patient.

The History of Scoliosis.—Robert W. Lovett presents a most interesting and entertaining paper, tracing the history and methods of treatment of scoliosis from the times of Hippocrates to the present day.

What to Do after Corrective Jackets Are Removed.—E. H. Bradford believes that the best method of correction of fixed spinal curves is by properly applied plaster jackets. But correction of the curve is not curing to the patient. Gymnastics are adjuncts in treatment, but not to be relied upon exclusively when a relapse is threatened. Check braces are of assistance if they prevent slumping and faulty attitudes. Such braces should not be waist or thorax compressing corsets. As there is a tendency to relapse during growth, inspection and treatment may be needed for a long period. Ugly, heavy, disfiguring appliances should not be applied for an indefinitely long period. To be honest with himself, the surgeon should in watching the most chronic of surgical ailments, keep accurate records and measurements of contour, flexibility, curve, and rotation to enable him to detect relapse definitely and to note gain positively.

The Rotation Treatment of Scoliosis.—A. Mackenzie Forbes advocates a method for the correction of scoliosis, the principle of which is the production of a physiological scoliosis induced by rotation, which is a direct counterpart to the original primary deformity. The correction can be accomplished with or without apparatus, the rota-
tion being secured by means of the arms and fixed with plaster of Paris. The rotation is best accomplished in flexion. The cast is fenestrated over contracted thoracic walls and pressure is provided over the bulging walls. A course of breathing exercises is recommended.

**Treatment of Lateral Curvature of the Spine by the Forbes Method.**—Z. B. Adams gives an explanation of the Forbes method by means of charts and photographs.

**Gymnastics for Crippled Children.**—Miriam T. Sweeney, in this paper, makes a plea for a consideration of gymnastics for orthopedic conditions and the enumeration of specific exercises for individual cases.

**Human Carriers in Poliomyelitis.**—R. B. Os-good reports a case in which the nasal secretion of a patient, two years after a primary attack of polio-myelitis, was injected intracerebrally into monkeys, and produced complete paralysis with typical pathological findings of anterior poliomyelitis.

**Spontaneous Fracture in Carcinoma of the Bones.**—G. W. Hawley reports three most interesting and instructive cases in which metastatic involvement of the bones complicated carcinoma of the breast. Numerous spontaneous fractures were noted, in all of which union was prompt and complete.

**Tendon Fixation—An Operation for the Prevention of Deformity in Infantile Paralysis.**—W. E. Gallie advocates a method of tendon fixation, which is accomplished by making an incision in the periosteum along the usual course of the tendon. The periosteum is stripped back for a quarter of an inch on either side of the incision. A trough is then gouged out of the bone, into which the tendon is placed, the periosteum is sewed over the tendon, and the suture is pressed through the tendon several times, to hold it firmly in place. The foot is held in plaster of Paris for two months.

**JOURNAL OF PHARMACOLOGY AND EXPERIMENTAL THERAPEUTICS.**

**Action of Serum on Perfused Heart of Rabbit.**

—A. R. Cushny and J. A. Gunn found that when the isolated rabbit’s heart is perfused with Ringer’s solution, the addition of blood serum, egg albumin, or starch solution produces changes in the heart beats consisting of preliminary stimulation and of subsequent depression, possibly with heart block and ultimate cardiac arrest. Evidence is at hand to show that the secondary depression is due to a diminution in the coronary flow, caused, in turn, by a direct action on the coronary vessels. The primary stimulant action may be due in part to a direct action of serum on heart muscle. The changes observed are probably due to an abnormal state of the heart and its vessels produced by prolonged perfusion with Ringer’s solution, and not to the formation of a poison in the perfusion fluid by the addition of serum, etc.

**Effect of Atophan and Novatophan on Endogenous Uric Acid Excretion.**—H. D. Haskins reports investigations carried out in twenty-one apparently healthy students. All had been on a purin free diet for one week before the drug was taken. In most cases the drug was given for a single day, the dose of atophan used being 0.5 gramme four times a day, and of novatophan, the same quantity five times a day. The results strongly suggested that the main effect of these drugs is to drain uric acid out of the blood, leaving the uric acid content of the latter subnormal. Atophan appeared somewhat more efficient than novatophan.

**Treatment of Experimental Beriberi with Extracts of Spinal Cord.**—C. Voegtlin and C. Towles found that an aqueous extract of autolysed spinal cord of the ox, from which coagulable protein has been removed, contains an antineuritic substance which cures symptoms of polyneuritis in rice fed birds, in daily doses corresponding to four grammes of dried cord. This substance, when added to a diet of polished rice, is capable of removing the nervous symptoms of the disease, but cannot reestablish a normal metabolism, nor enable the affected birds to recover their body weight. The antineuritic substance is liberated through autolysis from the nerve fibre. A ten times greater amount of nonautolysed cord extract saved but few animals from death.

**Action of Nitrites and the Digitalis Group on Isolated Coronary Artery.**—C. Voegtlin and D. I. Maehl, studying the effects of various drugs on rings from the coronaries of the ox and pig, placed in warm oxygenated Locke’s solution, found that digitonin and digalen produce relaxation, while digitoxin, digitalin, and bufazin cause constriction, of the coronary arteries. Digitonin is probably responsible for the dilatation produced by digalen and the infusion of digitalis. All the nitrites produce prompt relaxation. The nitrites and digitalis bodies can antagonize each other in their action. Whenever, clinically, coronary spasm is to be guarded against, it seems advisable to employ the digitonin containing preparations or simultaneously give nitrites. The observed dilator action of the latter tends to explain their favorable action in angina pectoris due to coronary spasm. No dilator effect was observed in the case of urethane.

**Reversible Action of Epinephrine and Kindred Drugs on the Bronchioles.**—F. L. Golla and W. L. Symes, using new plethysmographic methods for investigating changes in the bronchiolar airway under the influence of drugs, observed that the action of epinephrine, tyramine, epinine, and some other amines and alkaloids, on normal bronchioles, is constriction. This constriction is not parallel to, and usually outlasts, the accompanying vascular constriction. It is abolished by urethane. After preliminary bronchiolar constriction has been brought about by curare, ergotoxine, apocodeine, pilocarpine, muscarine, or physostigmine, the action of epinephrine, tyramine, etc., is reversed, bronchiolar dilatation taking place. The tracheal muscle was found by the authors to differ in its reactions from the muscle tissue of the bronchioles.

**NEW ORLEANS MEDICAL AND SURGICAL JOURNAL.**

**On Pelvic Infections, with Special Reference to the Needs of the General Practitioner.**—S. M. D. Clark speaks of the frequency of pelvic infections, and selects for discussion some of the more
common phases of the subject. The location of the
genital organs renders them peculiarly prone to in-
fec tion. The vaginal canal of every parturient
woman is fortunately possessed of a wonderful
process of defense in checking infection from
spreading to distant areas, and the reason we so
do
cieldly see a widespread ascending vaginal sal-
lit is is on account of a phenomenal infiltration, ede-
ma, and swelling blocking the routes of infection.
The case is different, however, with the cervix; it
has more lymphatics than any other part of the
generative organs, and he is convinced that as a
gateway of infection it has not been given due con-
sideration. Its lymphatics drain into the cellular
tissue interposed between the folds of the broad
ligaments, the parametrial, the perivesical, and the
peri rectal tissues. The infection strikes directly
through, and in many cases of puerperal infection
the cavity of the uterus is absolutely uninvolved.
The body of the uterus not being nearly so richly
supplied with lymphatics, it is only in the most viru-
ulent type of infection that we see the bacteria pene-
trating its walls and producing a general peritonitis,
thrombophlebitis, septi c emboli, endocarditis, and
death. While the interior of the puerperal uter-
us offers a perfect culture medium, as the infect-
ing organism is less virulent the trouble is often
confined to the uterus, with a sympathetic broad
ligament swelling, which, if left alone, will recover
spontaneously. If it is ascertained, from minute
examination of the placenta and membranes, that
the cavity is empty, curetting is criminal. Given a
case in which one is positive that the uterus is
empty, no intrauterine douching is called for, and,
as regards local treatment, a masterly inactivity is
the keynote of success. In the general treatment
the patient should be drenched with water, procto-
clysis is of service, and careful attention should be
paid to the action of the skin and bowels, while
abundant, liquid, nutritious food should be admin-
istered. When the cavity of the uterus is believed
to contain infecting material, it should be emptied
with the least possible traumatism and packed with
gauze soaked in normal tincture of iodine. This
should be removed in twenty-four hours, and two
vaginal salt douches given daily. After referring
briefly to infections of the tubes and the veins, the
author takes up nonpuerperal infections, such as the
gonococcie, the streptococcie, and the staphylococcie.
Here, he says, absolute physical, sexual, and
mental rest, combined with supportive treatment
and active elimination, give many splendid results
where formerly the organs were sacrificed. This
conservative and rest plan of management has not
only a curative side, but is also a valuable agent in
the preoperative and postoperative care of the pa-
tients.
Emetine Hydrochloride in the Treatment of
Amebic Dysentery.—Randolph Lyons, having
already published a report of six cases, in this pa-
er gives a résumé of the previous cases and also
presents his experience with this treatment in an
additional case. Of the seven cases reported, all
were apparently cured except one, which was hone-
less from the beginning. He has recently given the
drug by mouth (in salol coated pills), as well as in
solution by hypodermic injection, in a severe case.
In summing up he says he believes that emetine hy-
drochloride may prove to be of great value in ame-
bic disease. Whether it will replace ippecac, which
is its parent, as a therapeutic agent, or will be found
more valuable in conjunction with it, remains to be
proved. Certainly in those cases in which ippecac
cannot be taken by the mouth the treatment will be
a boon.
The Operative Treatment of Vesicovaginal
Inaccessible Fistule.—The essential features of
the procedure which F. W. Parham has employed
with success are: 1. Liberal dissection of the vagi-
nal mucous membrane, so as to mobilize the bladder
freely and bring the fistula within reach. 2. Be-
ning the dissection well forward, just behind the
urinary meatus, where the natural lines of cleavage
make it possible to separate easily the vaginal mem-
brane from the bladder wall. 3. The use of a lever
in the bladder to push down the wall, so as to make
the fistula accessible for suture.

CLINICAL CONGRESS OF SURGEONS OF
NORTH AMERICA.

GEORGE EMERSON BREWER, M. D., PRESIDENT.

(Continued from page 1042.)

The Radiotherapeutic Treatment of Benign
and Malignant Tumors.—Doctor KRONIG, of
Freiburg, Germany, stated that the domain to
which radiotherapy was well adapted was in the
treatment of fibromyoma of the uterus. Radiothe-
rapy of fibromyomas could now be undertaken in a
most thorough manner. They had made use of the
Röntgen ray treatment exclusively in a number of
cases. They had also used mesothorium combined
with Röntgen rays, and also mesothorium, in the
treatment of these tumors. High doses were by no
means necessary in every case of this kind. In a
certain proportion of cases quite as good results
had been obtained with proportionately small doses.
Women over forty-five years of age were more
easily influenced by Röntgen rays and the desired
object, amenorrhoea, with a diminution in the size
of the tumor, had been accomplished earlier in
these cases than in younger individuals; neverthe-
less they found cases among women over fifty years
of age who could not be successfully treated with
small doses. They had never witnessed any un-
pleasant effects from high doses. High doses had
given good results. They had treated 350 cases of
myomas of the uterus with Röntgen rays. The
chief aim of radiotherapy was: 1. Diminution in
the size of the tumor; 2. diminution in the se-
vity of the hemorrhage, but without absolute
amenorrhoea. They had many times attained this
end, especially in younger individuals, but they had
to confess that they had seldom gained the desired
object. Shrinkage of the tumor began only when
amenorrhoea was gradually established, and more-
over relapses were frequent if menstruation had
not completely ceased. The X ray treatment of
myoma was comparable with supravaginal ampu-
tation of the uterus. Radiotherapy for myomas of
the uterus was in every way far superior to the oper-ative treatent of myoma by means of total extir- 

pation or by supravaginal amputation of the myo- 

matous uterus.

They had treated 254 cases of cancer with Rönt- 

gen rays and radium. The material included those 

cases treated for the prevention of the secondary 

growth after operation for carcinoma, as well as 

those cases in which radiotherapy for carcinoma 

had been used therapeutically. Of this number 150 
cases were treated on purely therapeutic lines and 

without operation. Of these 150 cases, 140 were 
treated with Röntgen ray and mesothorium com-

bined, while in ten cases the Röntgen ray alone was 

used. Of sixty-four cases of carcinoma, forty-

three cases they had treated for the prevention 
of secondary growth almost exclusively with un-

filtered Röntgen rays, while twenty-one cases were 
treated partly with filtered and partly with unfil-
tered rays. The difference was striking. While 

thirty-two out of forty-three patients died of 
carcinoma, they had been able to follow the sub-

sequent history of twenty out of twenty-one cases, 

and found that sixty per cent. of the recurrences 

occurred the first year after operation. 

Recurrent cancers had been treated with radio-

active substances. Of the 140 cases which they had 
treated with Röntgen rays and mesothorium, three 
groups of carcinomas should be differentiated: 1. 

Those in which carcinoma had not spread beyond 

the primary focus, as in cases in which operative 

removal of the cancer was still possible. 2. Those 
carcinomas in which a new growth had already ex-
tended beyond the primary focus into the neighbor-
ing tissue, and in cancer of the cervix where 

the carcinomatous growth had spread into the parame-

trium and glands, so that operation was out of 

question. 3. Those carcinomas in which additional 

metastases were already present. 

So far as their investigations up to date went, 

they had not succeeded by means of the technic em-

ployed in effecting a cure in a single case of meta-

tastic carcinoma. It was quite possible to produce 

remarkable regressions and checking of the car-

cinomatous metastases by means of intense radia-
tion of Röntgen rays and radium, but in all cases 
at the present time carcinoma had later on spread 

further. They could not say they had saved a sin-

gle patient. In the second group of cases the ma-

jority of the patients were at the present time im-

possible of cure, in spite of any known Röntgen 

and mesothorium radioactivity. 

Dr. Howard A. Kelly, of Baltimore, stated that 

he had used radium in 306 cases, of which 188 

were of malignant growths, including tumors 

from all parts of the body—mouth, throat, neck, 
nose, lower part of the abdomen, the uterus, 

etc. He had treated forty cases of cancer of the lower 

part of the uterus, where the disease was apt 

to spread rapidly, and the cases were consid-

ered hopelessly advanced and inoperable, and in 

three of them after extensive operation, radium 

was used. Under the usual methods a speedy re-
currence would have taken place without question. 

In those three instances there had been no recur-

rence and health had been fully restored. He had 

also had four cases where no operation could be 
done on account of the general condition of the 

patients. Two of the patients had had diabetes, 

and one Bright's disease, and the other a serious 
aliment which contraindicated operation. In those 
cases apparently a cure had been brought about. 

He had had two cases of cancer of the larynx, in 
one of which the patient had been well for months, 

and in the other the patient appeared to have re-
covered, but was still under observation. The 
speaker stated if we could have an abundant supply 
of radium, its use for superficial cancer would yield 
better results than surgery. It would cure cases 
of cancer of the nose, eyes, lip, etc., where surgery 
would mutilate.

Dr. C. J. Gauss, of Freiburg, Germany, discussed 

the technic of radium and mesothorium in the treat-

ment of fibroid tumors and cancer of the uterus.

The Diagnosis of Lesions of the Upper 

Urinary Tract.—Dr. Hugh Cabot, of Boston, 
laid down four propositions and defended them: 

First, we had at our disposal methods of diagnosis 
of lesions of the upper urinary tract which were 
of extreme accuracy. Second, those methods of 
diagnosis were of value not only in lesions of the 

urinary tract, but in the differential diagnosis of the 

abdominal lesions. Third, that those methods of 
diagnosis were not being used with that frequency 

which their value entitled them to, and therefore a 

large percentage of errors was being made. Fourth, 

that those methods of diagnosis required skill and 
judgment in their application, and without that skill 

and judgment they were dangerous. Doctor Cabot 
reported and showed numerous slides of cases illus-

trating errors that have been made in diagnosis.

Dr. Arthur D. Bevan, of Chicago, stated that 

his solution of the difficulties presented by Doctor 

Cabot would be that we needed in each clinic a 
complete organization, a surgeon, a cystoscopist, a 
radiologist, a competent laboratory worker, and a 
good internist. It was this sort of organization 

that should employ the new methods of diagnosis 
in lesions of the upper urinary tract rather than 
some special surgeon. In making a diagnosis of 

lesions of the upper urinary tract, and in practically 

all abdominal work, the evidence which it was des-
irable to obtain could be easily grouped under four 

heads according to their value: First, the history: 
of a given case of lesions of the upper urinary tract 
was more valuable than anything else. Second, 

proper physical examination, including under the 
term physical examination an examination for tu-

mors, dilatation of the colon with air, cystoscopic 
examination, catheterization of the ureters, x ray 
pictures of the region with or without collargol. 
Third, the laboratory findings. Fourth, the im-
portance in a limited number of cases of explora-

tory operation in making a diagnosis.

Pyloroplasty.—Dr. J. M. T. Finney, of Balti-

more, read a paper in which he related his experi-

ence with pyloroplasty extending over a period of 
fourteen years. After he had given the results in 

150 cases in which he had operated, he said the 

immediate as well as final results were most en-
couraging. While partial gastrectomy and 
goastrectomy were the operations of choice, never-
theless, on account of its simplicity and because of 
the satisfactory end results, he believed pyloro-
plasty would continue to retain its position as a safe and useful procedure.

Dr. E. W. Andrews, of Chicago, stated that the statistics of pyloplasty, as given by Doctor Finney, were equal to those of any series of cases from any clinic where ordinary gastroenterostomy had been done, both as regards success of the operation and mortality.

Report of the Cancer Campaign Committee.—Dr. Thomas S. Cullen, of Baltimore, chairman, first made mention of radium, saying that few surgeons in the country had sufficient of the material to give it a thorough trial, since it appeared that extensive doses sometimes cured when smaller amounts had but little effect. Radium (as suggested by Charles L. Parsons) should be standardized so that the buyer would know what he was paying for. Only time would tell what proportion of cases could be cured with radium. At present early surgical procedure afforded the best chance for cure. While the results obtained from radium had to be taken into consideration, at the same time, the men who had reported the best results were still urging early operation whenever possible. When people once understood the nature of cancer they would gladly avail themselves of surgical aid. In the past decades attempts to instruct the physicians alone had not produced any decisive results. Hence they had to go to the people at large through the newspapers and magazines. Many popular articles had already appeared. The press had responded nobly to their appeal. As a result the patients were coming earlier. Still there was need of further dissemination of knowledge by means of lectures on hygiene in women’s clubs, factories, and elsewhere. Further, better records had to be kept, hospital statistics had to be carefully analyzed so that accurate deductions could be drawn from them; they had to have surgical pathologists to aid in diagnosis. Thorough operations had to be insisted upon as soon as the diagnosis of cancer was made. All modern methods of recording data had to be utilized in hospitals. Patients who had been operated upon had to be followed up and the results recorded. Cancer of the uterus was one of the most frequent forms of cancer in women. There were two chief forms of cancer of the uterus, cancer of the neck of the organ and cancer of the body of the uterus. The first symptom of cancer of the uterus was bleeding, and as the disease progressed and parts of the cancer broke down the discharge became offensive. Cancer of the neck of the uterus was by far the more common and could be readily detected by the use of simple instruments. Cancer of the body of the uterus could not be seen and could only be definitely determined by scraping away some of the material and examining this with the microscope. The material removed was suitably hardened and shavings about 1/300 of an inch thick were made. These were stained and examined with the microscope. The picture of cancer was totally different from that found in health, and the expert with the microscope could usually tell with absolute certainty whether the disease was cancer or not. The picture of cancer as viewed with the microscope was as different from that noted in the healthy organ as were two totally different patterns of wall paper. In the years past few cases of cancer of the womb were cured. Now from twenty to twenty-five per cent. of patients suffering from cancer of the neck of the uterus that were operated upon were permanently relieved. Some of these patients were well thirteen or more years after operation. The results following operations for cancer of the body of the uterus were much more comforting, at least two thirds being permanently cured. These results were a wonderful improvement on those of twenty or thirty years ago when nearly all died. Cancer of the uterus was most common between the thirtieth and fiftieth years, but had occurred in early womanhood and might also attack the aged. Any woman with bleeding that could not be definitely explained ought to be examined at once, and any patient having much bleeding at the time when the “change of life” occurred ought to seek medical aid forthwith. The bleeding might be due to cancer or might be caused by some simple ailment. When women realized what splendid permanent results might be obtained by early operation and fully appreciated the necessity of finding out just what was the matter with them, instead of procrastinating until the disease was far advanced, then the proportion of permanent cures would be greatly increased.

Publicity and Ethics.—Mr. Samuel Hopkins Adams, of New York, stated that much could be done in health education of the public, whether in cancer, in tuberculosis, in the venerable plagues, or in epidemic diseases, by lectures; but more could be accomplished by the magazines. The universal agency, however, of popular education was the daily press. Between that great agency of enlightenment and the medical profession there had been raised a barrier fraught with difficulty, the barrier of the unwritten law of the profession, which said to the doctor, “Thou shalt not appear in print!” The daily paper, with all its sins, was the one agency by which the medical profession could attain immediate, positive, and direct universal education—a saturated solution of enlightenment. Nothing else would do it. There was no sacred reticence required of a doctor other than the reticence that guards the privacy of his patient. The time had come when the old obsolete ban of silence should be lifted and the propaganda should go on through the agency best fitted to spread it, the daily newspapers.

Publicity and Education through the American Society for the Control of Cancer.—Dr. Edward Reynolds, of Boston, stated that we knew now that in many situations the malignant diseases were preceded by what we might call, for the sake of brevity, a precancerous state, such as the adenomatous stage in the development of cancer of the body of the uterus. We were able to distinguish this condition with certainty in many forms of the malignant disease whenever the patient came to us in that early stage, and we knew that in that stage a radical operation promised in many situations of the disease an almost absolute immunity from recurrences, as opposed to certain death if the patient reached us too late. We were individually
doing our best to publish to the world the importance of early diagnosis, but collectively, and as a profession, we had as yet done nothing. We could exert but little influence upon the over conservative, the timid, and the other weak and halting members of the profession, but our patients, the great lay public, had a right to demand that every member of the profession should be forced to do his duty in this direction. We were each of us individually doing our best to accumulate further information about the disease, but as a profession we had made no organized effort toward the systematic and widespread investigation which was the necessity of the day. We had not as yet had the organization, the money, nor the trained workers which were essential to success. The surgical profession was more than ready to give its time and its trained ability to the work, but the profession formed neither a large nor, as a whole, an affluent proportion of the community. The money for any such widespread organization must come from the numerous and more wealthy laity, for whose benefit this movement was being inaugurated.

The American Society for the Control of Cancer was a body which was composed of prominent members of the profession and of influential members of the laity. It was actively at work in perfecting a widespread organization of national scope for the active prosecution of this campaign. It had already been guaranteed and indeed, for the most part, had already in cash the large amount of money which was necessary even for initial expense of the organization. It had already under salary a general executive secretary whose past career was a guarantee of his possession of the necessary power of organization. It planned to work in cooperation with all the existing organizations in the study of cancer and in the promotion of the necessary publicity of all the points on which we already had assured knowledge. It had already been assured of hearty cooperation from the more important of these preexisting bodies, and had received the endorsement of all, or nearly all, of the great national medical associations. It asked the sympathy and effective aid of every member of the profession and of every interested layman and laywoman. It was essential to so large an undertaking as this that its initial organization should receive the time and attention and the very large amount of labor which was essential to its perfection. He believed we were rapidly approaching the day when we should put our appeal for aid, in both money and work, before every one and before the public, in the concrete form that would make rapid progress possible.

Education and Publicity through the Council on Health and Public Instruction of the American Medical Association.—Dr. Frederick R. Green, of Chicago, stated that our knowledge of the causes of disease, its method of transmission and the possibility of its prevention imposed a duty on the profession toward the public, which was being neglected as an important direction of the medical profession. Since the scientific medical men alone possessed the technical knowledge necessary for the handling of such problems, we must look to them for such knowledge. But when an effort was made to apply this knowledge for the production of practical results, it was found that while the specific cause of a disease and the like history of the organism might be known in the most minute detail, the prevention or suppression of the disease was a social, and not a scientific problem. Increasing knowledge of the cause of diseases, perfection of methods for their prevention, as well as the recognition of the paramount importance of regulation of social conditions for such prevention, made it necessary that there should be an educated public sentiment back of all of our efforts for disease control. The real force in this country and the only effective force was public opinion. Laws were the crystallization of public opinion and not one of its formative influences. When this principle was fully recognized, we should cease to advocate the adoption of mandatory laws without first creating a discriminating and intelligent public opinion on the necessity and importance of such regulation. If the education of the public was properly carried out, the number of laws required would be greatly diminished and the effectiveness of those in force would be proportionately increased. The necessity for public instruction on the prevention of disease had been recognized by practically all of our State boards of health, and by many of our municipal health departments as well as by the various Federal bureaus working on public health and allied subjects. It had also been recognized by the organization of a large number of special voluntary societies, composed of those interested in some social problem and devoted to the arousing of public sentiment on this specific subject.

What could the Council on Health and Public Instruction of the American Medical Association do to enlighten the public on this subject? The answer was obvious. It could place at the disposal of the American Society for the Control of Cancer and the Committee of the Clinical Congress of Surgeons of North America all of the resources of the council on Public Health Education. Through the Press Bulletin, suitable material on the subject could be placed in the hands of five thousand editors, without any cost to the society or to the committee. Through the Speakers Bureau addresses could be given to the public on Cancer and Its Menace. Through the Bureau of Literature, local pamphlets and leaflets on this subject could be distributed. Later on through the Lantern Slide Bureau of Exhibits material on cancer and its control could be placed before the public. The agencies at work on this problem at present were the American Society for Control of Cancer; the Committee of the Clinical Congress of Surgeons of North America, and the Council on Health and Public Instruction of the American Medical Association.

The work to be done seemed to be threefold and to be peculiarly adapted to these three organizations. The first thing was to interest the public and especially the wealthy and influential public in the problem of the control of cancer. This was a movement for the public welfare, and there was no reason why the public should not assume part of
the expense. This was the work for which the recently organized Society for the Control of Cancer was admirably adapted. The second necessity was the careful investigation of the entire problem of cancer, its age, its race and sex incidence, its relative frequency in different occupations and locations, and all of the clinical facts connected with its appearance. The speaker stated that there was to-day in the records of our different hospitals throughout the country an enormous mass of un- digested material on this subject. This was clearly a clinical and surgical problem. The third requirement was the distribution to the public of the results of such an investigation. This was obviously a task for the Council on Health and Public Instruction of the American Medical Association, representing as it did the organized profession of the entire country. Through its machinery, it could, without any additional expense, place before the public any information which might be desired on this question.

(To be continued.)

Letters to the Editor.

"AUROMETER." 173 Lexington Avenue, New York, November 22, 1913.

To the Editor:

In to-day's issue of your esteemed JOURNAL Dr. M. Lubman describes his new instrument which he calls aurometer. At first sight I thought this hybrid word might mean gold measure from the Latin aurum and the Greek meter, but on the face of it I find that is still worse; the author has made the composition from the Latin aurum and the Greek meter, and this would be an ear measure but not an instrument for testing the hearing as the author means to say, for hearing in Latin is audire. The medical lexicons which I have on hand give acoumeter and acouometer from acouo to hear, and this is not incorrect but better to make the composition instead from the verb acouo from the noun acous, eos and say acouometer. I hope this will kill the new word monstrosity stone dead. A. Rose, M.D.

Book Reviews.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

Doctor Woglon has made a very useful compilation of the many articles that have dealt with the experimental side of cancer research. The various phases of the matter are ably presented and the views of the investigators clearly set forth. The more, however, that one reads the more evident it becomes that little progress has been made in such an explanation of the neoplastic processes. Much work has been done and the various phases have been determined but as yet the interpretation of these facts has not been accomplished. It still remains for some one to find the key to the riddle and clear up the situation for us. To one interested in the subject of cancer research this volume might be considered almost essential as it is really an encyclopedia; there seems to be no point neglected. The one thing that is open to criticism is the unwieldy form in which these reports of the George Crocker Special Research Fund are prepared. The reader has to suffer for the large and useless margins. The articles contained in this report come from the departments of zoology, surgery, clinical pathology, and biological chemistry. Most of these have been published elsewhere; these are the facts that are original in that this is their first appearance. One of the most interesting is that by Rhodenburg, Bullock, and Johnson on The Relation of Certain Internal Secrec- tions to Malignant Tumors, although their results are to a large extent negative, the value of this report lies in the bringing together of so large an amount of work in order that one who is interested in the subject may readily review the literature. Like the other volumes this report is published in a very unwieldy form.

The recent edition of this valuable work shows marked evidence of careful revision of the text; many facts having been altered by the addition of much new material of significant importance. The use of the Röntgen ray and its value as a diagnostic agent is ably discussed; Pas- sow's plastic in cases of slow healing following the radical mastoid operation is thoughtfully presented; the blood examination in sinus thrombosis and the functional testing of the labyrinth have received careful attention; while it has been found necessary again to completely revise the chapter dealing with the opening of the labyrinth. In the present edition the authors make a more marked effort to justify his advocacy of early and free paracentesis. His classi- fication of the indications for this operation in the early pages is worthy of note, the advantages to be gained thereby, in certain specified conditions being evident. The work is divided into two main headings, viz.: The Operations in Middle Ear Suppurations, and The Operations in Intracranial Complications of Otic Origin. The former is further divided into operations on the tympanic mem- brane and middle ear cleft. This comprehensive chapter of the work nearly occupies one third of the book; the opening of the labyrinth. The subdivision of the latter consists of the operation for extradural and subdural abscess, the operative treatment of the cerebral sinus, the evacuation of brain abscess, and the operation in serous and purulent meningitis. The plates are expertly executed and add much to the value of the text in elucidating certain operative procedures.

This book is illustrated by 199 well executed cuts, contains a clear and well arranged table of contents, a comprehensive index, and a complete bibliography of foreign writers, whose opinions and experiences are referred to in the text and make reference to works on this subject a simple matter. The chapters on guns and ammunition take up very thoroughly the manufacture of firearms and their development and improvement during the century up to the present improved types.

We have here a practical description of every grade of firearm in use, from the revolver to the siege gun, with the composition of the powder, charge, and damage of each missile. The development of the modern magazine rifle is given with the various stages in the de- velopment of bullets to the steel jacketed, pointed type. The range and rapidity of fire of the rapid machine gun is given as is the composition and effectiveness of shrapnel and grenades. The subject matter on firearms and muni- tions is so thoroughly prepared and so comprehensive that it offers a high grade of scientific and practical instruction. The adjective practical war in this volume is particularly valuable since it expresses conclusions based on actual experience and serv-
ice in the Russo-Japanese war. There is a systematic description of varieties of wounds caused by the various types of missiles. When the body is taken up in turn, and the nature of the wounds discussed. Under the title of Wound Infection, the author warns against the probing of aseptic wounds, against the unnecessary packing of wounds, and against irrigating sterile wounds or washing the surrounding tissues. The use of antiseptics such as bichloride of mercury, carbolic acid, and iodform, in the treatment of wounds, is utterly condemned. He favors organic solution of mercury, and dusting powders. In general, he uses a preparation containing resin. This is used for almost all antiseptic purposes, especially for disinfection of the skin surrounding wounds.

The greatest stress is laid on the principle of fixation, both of the wounded member, the entire body, and the bacteria on the skin surface. Plaster of Paris dressings seem a favorite method also the use of adhesive plaster. The following points are emphasized: First aid dressings should not be changed at sanitary stations in the rear unless antiseptics (bichloride) have been used, or unless the dressings are bloodsoaked or have become loose. Morphine with or without atropine is the best treatment for shock and for the fatigue accompanying transportation. The treatment of the various types of wounds of each part of the body is given in detail and is excellent in its practicability and thoroughness.

The character of the treatment indicated at each of the successes is a field diagnosis of the wound, and its cause, for wounds ever of every part of the body. The treatment given for wounds of the skull and of the abdomen and its contents is especially valuable, giving also the indications for absolute rest, transportation, or operative interference.

The work is really a condensed textbook of the treatment of wounds of every part of the body under conditions of latterday warfare, embodying therefore the latest methods developed by actual observation in the field. The work will prove invaluable to medical officers with little or no experience in actual warfare, and will be interesting and instructive to more experienced officers. The lessons it teaches would certainly be of value to those in civil life who are frequently called upon to treat wounds made by missiles, especially those of firearms.

The author deals with his subject in a very clear and technical manner so that a layman could readily understand the essential points in determining the purity of a given water supply. The varieties of water supplies and their chemical constituents are briefly reviewed, as are the methods of bacteriological, chemical, and microscopic examinations.

Women's Notes, published by Street and Smith, is the latest addition to the list of popular magazines. Our women physicians will meet in its pages such favorites as Frances McIntyre, Mary Matthews, Maragaria Spalding Gerry, Anne O'Hagan, Helen Green Van Campen, and Anna Katherine Green, and we think that our men friends too need not be afraid that this new magazine is too milk and watery for them. Why have we not an Agnes Repplier among our women doctors? She would prove to be a redoubtable rival to Oliver Wendell Holmes. And what a heroine for a romance a woman doctor would make! * * *

The Industrious Chevalier and his Lady, by S. Squire Sprigge, the editor of the Lancet, is a capital series of short stories published some ten years ago in England. It was a great surprise recently to see these tales appearing serially in one of the popular magazines, although they have been sufficiently wild and well and, as such, have been recognized, or perhaps they were a trifle old fashioned. The hero drives in hansom and coupes, a mode of progression quite too slow for modern readers. Mr. Sprigge's talents as a teller of stories are great and the Lancet, as has been universally recognized, was fortunate in securing a man of his literary ability to cultivate taste as editor. * * *

Many of our readers will remember the mystery of the Marie Celeste, the ship which was found abandoned, but without any signs of disease or loss of life, in 1872. Many writers of fiction chose to write accounts of this strange affair. In the Sirand for December the true history is given by a survivor, Abel Fosdyk, under unusual circumstances. We are convinced that this solution is the true one, and actually transcends imagination.

Meetings of Local Medical Societies.

MONDAY, DECEMBER 1st.—Clinical Society of the New York Nose, Throat, and Lung Hospital; German Medical Society of the City of New York; Brooklyn Hospital Club; Roswell Park Club, Buffalo; Hornell Medical and Surgical Association; Utica Medical Library Association; Niagara Falls Academy of Medicine; Practitioners' Club, Newark, N. J.; Hartford, Conn., Medical Society.

TUESDAY, DECEMBER 2d.—New York Academy of Medicine (Section in Dermatology); New York Neurological Society; Society of Foreign Physicians; Clinical Society of the West Side German Dispensary and School for Clinical Medicine; Buffalo Academy of Medicine (Section in Surgery); Ogdensburg Medical Association; Oswego Academy of Medicine; Syracuse Academy of Medicine; Medical Association of Troy and Vicinity; Long Island Medical Society; Amsterdam City Medical Society; Lockport Academy of Medicine; Bridgeport, Conn., Medical Association.

WEDNESDAY, DECEMBER 3d.—Long Island Society of Anesthesiasts; Brooklyn Society for Neurology; Bronx Medical Association; Society of Alumni of Bellevue Hospital; Harlem Medical Association; Schenectady Academy of Medicine; Elmira Academy of Medicine.

THURSDAY, DECEMBER 4th.—New York Academy of Medicine (stated meeting); Dansville Medical Association; Brooklyn Surgical Society; Practitioners' Club, Buffalo; Geneva Medical Society.

FRIDAY, DECEMBER 5th.—New York Academy of Medicine (Section in Surgery); New York Microscopical Society; Gynecological Society, Brooklyn; Manhattan Dermatological Society; Practitioners' Society of New York; Corning Medical Association; Saratoga Springs Medical Society.

Official News.

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending November 19, 1913:

Burkhalter, John T., Passed Assistant Surgeon. Directed to proceed to Washington, D. C., and report to the chairman of a board of medical officers convened to meet at the bureau, December 1, 1913, for examination to determine their fitness for promotion to the grade of surgeon. Cumming, H. S., Surgeon. Directed to proceed to Philadelphia, Pa., to arrange for sailing of steamer Bratton, which is to be brought from that port to Washington, D. C., for use in connection with the investigation of the pollution of the Potomac River. Currie, Donald H., Surgeon. Directed to proceed to Seattle, Washington, for conference with surgeon B. J. Lloyd on laboratory operations in plague work. Earle, Baylis H., Passed Assistant Surgeon. Directed to proceed to San Francisco, Cal., and to report to the chairman of a board of medical officers convened to meet at the Marine Hospital, December 1, 1913, for examination to determine his fitness for promotion to the grade of surgeon. Foster, A. D., Passed Assistant Surgeon. Directed to proceed to Wilkesboro and other places in the State of North Carolina.
after conference with the secretary of the State Board of Health, for investigation of the prevalence of trachoma and other infectious diseases among the mountain population of that State. Holt, J. M., Passed Assistant Surgeon. Directed to report to the chairman of the Board of Senior Medical Officers convened to meet at the Marine Hospital, San Francisco, Cal., December 1, 1913, for examination to determine his fitness for promotion to the grade of surgeon. McMullen, John, Surgeon. Directed, in connection with the campaign against trachoma in Kentucky, to proceed from New York and Philadelphia to observe latest operative procedures in eye clinics; thence to Jackson and other points in Kentucky to determine the best location for ambulatory treatment and dispensary; also in connection with this work, to address the common school for health officers at Louisville, Ky., December 8 to 10, 1913, on trachoma work in Kentucky. Neil, M. H., Assistant Surgeon. Directed to attend the meeting of the Third National Conference on Housing in America at Cincinnati, Ohio, December 3 to 5, 1913. Oakley, J. H., Surgeon. Directed, at the request of the secretary of the State Board of Health of Kentucky, to proceed to Rochester, Ky., on Green River, to investigate reported outbreak of smallpox. Phelps, Earle B., Professor. Directed to proceed from New York, N. Y., to Boston, Mass., and vicinity and advise with local health authorities relative to the conduct of investigations of smallpox administration. Simpson, William G., Surgeon. Detailed for duty in the Assistant Surgeon in charge of the Division of Medical Hospitals and Relief, effective November 14, 1913. Warren, B. S., Surgeon. Directed to cooperate with the medical and sanitary officer of the Bureau of Engeneering and Printing to ascertain the cause of high rate of physical inefficiency of certain classes of employees. Wilson, Robert L., Passed Assistant Surgeon. Directed to proceed to Washington, D. C., and report to the chairman of a board of medical officers convened to meet at the bureau, December 1, 1913, for examination to determine his fitness for promotion to the grade of surgeon.

Boards Convened.

Board of commissioned medical officers convened to meet at the bureau, Monday, November 17, 1913, for the purpose of preparing questions for the mental examination of certain passed assistant surgeons to determine their fitness for promotion to the grade of surgeon. Detail for the board: Assistant Surgeon General W. G. Simpson, chairman; Assistant Surgeon General W. C. Rucker, member; Assistant Surgeon W. H. Warren, recorder.

Board of commissioned medical officers convened to meet at the Marine Hospital, San Francisco, Cal., Monday, December 1, 1913, at 10 o'clock a. m., for the purpose of conducting an examination to determine the fitness of certain passed assistant surgeons convened to meet at the grade of surgeon. Detail for the board: Surgeon R. M. Woodward, chairman; Surgeon J. D. Long, recorder.

United States Army Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Army for the week ending November 22, 1913:

Ashburn, Percy M., Major, Medical Corps. On his arrival in the United States, will be granted a leave of absence for one month. Barber, J. R., Captain, Medical Corps. Has been granted a twenty days' leave of absence. Brechemin, L. Jr., Major, Medical Corps. Relieved from temporary duty at Camp Douglas and ordered to proceed to Fort Preble. Culler, Robert M., Captain, Medical Corps. The leave of absence granted has been extended to December 5, 1913. Hillman, C. C., First Lieutenant, Medical Corps. Granted twenty days' leave of absence on November 19. Mullins, T. K., First Lieutenant, Medical Reserve Corps. Resignation declared effective November 20, 1913. Rutherford, H. G., Major, Medical Corps. Ordered to New York, N. Y., to assume charge of the Medical Department exhibit at the New Grand Central Building, New York, November 20. Stimpson, John, Medical Corps. Ordered to Fort Niagara, during the absence of Major Shockley. Truby, W. F., Major, Medical Corps. Announced as sanitary inspector and assistant to division, Third Division, San Francisco, Cal. Van Kirk, H. H., First Lieutenant, Medical Corps. Relieved from duty at Calexico, California, and ordered to the Presidio of Monterey. Weed, Mark D., Captain, Medical Corps. Granted twenty days' leave of absence.

United States Navy Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Navy for the week ending November 22, 1913:

Benton, F. L., Surgeon, Medical Corps. Detached from duty in the Army to the Navy, ordered to the receiving ship, Navy Yard, Norfolk, Va. Bostick, J. B., Assistant Surgeon, Medical Reserve Corps. Ordered to the naval training station, San Francisco, California. Garton, W. N., Surgeon, Medical Corps. Detached from the Hornet, U. S. Navy, ordered to the Kearns. Greene, J. B., Assistant Surgeon, Medical Reserve Corps. Commissioned from October 15, 1913. Hibbett, C. T., Medical Director, Medical Corps. Placed on the retired list on November 9, 1913, in accordance with section 1444, revised statutes, upon reaching the age of sixty-two years. McDonell, W. N., Passed Assistant Surgeon, Medical Corps. Ordered to the Naval Hospital, Annapolis, Md. Thompson, J. G., Surgeon, Medical Corps. Detached from the Albatross and ordered to the Pacific Reserve Fleet Toulon, J. A., Passed Assistant Surgeon, Medical Corps. Detached from the Ozark and ordered to the Seventy Williams, R. B., Surgeon, Medical Corps. Detached from the Ozark, ordered to the Naval Hospital, Norfolk, Va.

Married.

Monahan—Thompson. In Rochester Lower Mills, Mass, on Tuesday, November 11th, Dr. Edward J. Monahan, of Revere Beach, and Miss Olive Thompson.

Died.

Collins. In Nashua, N. H., on Sunday, November 16th, Dr. Charles S. Collins, aged sixty years. Collins. In Springfield, Mass., on Friday, November 14th, Dr. Edgar C. Collins, aged fifty-six years. Derdiger. In Chicago, on Wednesday, November 12th, Dr. Aria Louis Derdiger, aged fifty-two years. Fisch. In St. Louis, Mo., on Monday, November 17th, Dr. Carl Fisch, aged fifty years. Jones. In Philadelphia, on Tuesday, November 18th, Dr. William B. Jones, aged seventy years. Kreider. In Mount Holly Springs, Pa., on Tuesday, November 11th, Dr. Daniel B. Kreider, aged thirty years. Lee. In New Castle, Pa., on Wednesday, November 12th, Dr. Charles H. Lee, aged seventy-three years. Lytle. In Iowa City, Ia., on Friday, November 7th, Dr. S. S. Lytle, aged seventy-two years. McDowell. In Vincennes, Ind., on Sunday, November 9th, Dr. Moredecai M. McDowell, aged sixty-nine years. McFarland. In Oil City, Pa., on Thursday, November 13th, Dr. James McFarland, aged eighty-seven years. Morin. In Chicago, Ill., on Friday, November 14th, Dr. Louis P. Morin, aged seventy years. Ryan. In New York, on Monday, November 17th, Dr. Philip X. Ryan, aged twenty-seven years. Sawtelle. In Malden, Mass., on Friday, November 14th, Dr. George B. Sawtelle, aged seventy-five years. Schwinn. In Houston, Texas, on Saturday, November 19th, Dr. Edwin R. Schwinn, aged twenty-three years. Scott. In Louisville, Ky., on Thursday, November 13th, Dr. Maria Guttermann Graff Scott, aged seventy-three years. Shippen. In Petersburg, Va., on Monday, November 21st, Dr. Horace H. Shippen, aged fifty-five years. Tinkle. In New London, Conn., on Thursday, November 20th, Dr. Horace H. Tinker, of New York, aged fifty-five years. Treadway. In Stamford, Conn., on Thursday, November 21st, Dr. Franklin Treadway, aged fifty-five years. Turner. In Corona, N. Y., on Sunday, November 16th, Dr. James Lawrence Turner, aged seventy-four years. Ullyot. In Pomona, Cal., on Friday, November 7th, Dr. Thomas Henry Ullyot.
Original Communications.

THE PHYSICAL, MENTAL, AND MORAL VIGOR OF OUR SCHOOL CHILDREN.*

Fragmentary Notes on How to Preserve and Increase It.

By S. Adolphus Knopf, M.D.,
New York,
Professor of Medicine, Department of Phthisiotherapy at the New York Post-Graduate Medical School and Hospital.

1. To preserve the mental and physical vigor of our school children, we must begin to work with the preceding generations, with prospective fathers and mothers, continuing while the child is still in utero, and of course also during infancy and the preschool age.

The need of teaching eugenics as well as eugenics to lawmakers, clergymen, and the mothers and fathers of the present and future generations must be evident to all those who have studied without prejudice the results of inferior parentage. No marriage should be performed without a certificate from a reputable physician showing that the persons seeking to be man and wife are not afflicted with any contagious, communicable, or infectious disease; that they are physically and mentally sound and are not blood relations. Habitual drunkards or habitual users of drugs, such as opium, cocaine, ether, chloroform, etc., should be prohibited from marrying. If a four weeks' course in the elements of eugenics and eugenics and the obligations of fatherhood and motherhood were required prior to the granting of a license, much misery, disease, and sorrow would be avoided, and the children of future generations would become a higher type of men and women.

But prior to this we should bear in mind the fact that every female child attending school may become a mother some time, hence it is during her school age that we should prepare her physically and mentally for her divine mission. It was this thought that prompted the English Speaking Conference on Infant Mortality, which met in London on the 4th and 5th of August, to pass the following resolution: "In view of the damage liable to be wrought in growing girls by injudicious stress of education, especially during puberty and adolescence, this conference feels bound to depre-
cate any form of education for girls which pays insufficient attention to establishing good bodily health and development and complete fitness for maternity and the practical care of a home."

Prospective mothers should be taught the hygiene necessary during pregnancy in order to assure the health of the child. They should be instructed in the care of infants.

Any physical defect of the child which can possibly be corrected should be corrected before the child enters school, and not after. It is during the preschool age that the child should be prepared to be physically and mentally fit to enter school.

2. We must teach parents that quality is better than quantity and that a large number of children underfed and of mental and physical inferiority means race suicide, while the reverse is race preservation.

To show the necessity of this, let me first take tuberculosis as an example. Estimating the annual deaths from tuberculosis in the United States at only 150,000, it is safe to say that at least 50,000 of these were children at the school age. They have died without having been able to give any return to their parents and to their community. Making the average duration of their young lives only seven and a half years, and estimating the cost to parents and the community at only two hundred dollars per annum, the community loses seventy-five million dollars because it has not prevented a preventable disease. This is both a fearful economic waste and sheer race suicide. The same may be said of the defective, feebleminded, and idiots. According to Clark and Stowell, who made a study of the mortality of 4,000 feebleminded and idiots on Randall's Island, the average age at which these unfortunate die is thirteen years. Think of the cost to the community of maintaining these thousands of individuals for thirteen years! It is interesting to note that on that same island, under the same management, a hospital for mentally normal children is conducted, and the mortality in this institution is only half (3.38 per cent.) of that of the feebleminded, which is 6.5 per cent. The lower the mentality, the greater the mortality. Thus, the lower grades, imbeciles and idiots, give a mortality three times that of the feebleminded, i. e., 19.6 per cent. In all the tuberculosis dispensaries where we have been able to examine the children of the tuberculous parents who attend these institutions, we found that fifty per cent. of these children were tuberculously infected.

*Read before the Fourth International Congress on School Hygiene, Buffalo, August 27, 1913.

infected. I recall here the case of a tuberculous street sweeper with, I believe, a weekly salary of $12, who on his thirty-sixth birthday was found to be tuberculous and on the same day had become the father of his twelfth child. Here eugenics and euthenics have both been at fault.

3. There must be the heartiest cooperation between the city council, school boards, school architects, school superintendents, teachers, and parents.

The city council which usually appropriates the money and thus, by holding the purse-strings, can actually control to a large extent the educational policy of the school authorities, should be imbued with the highest but also most practical idealism tending to further the best educational interests. Council and school boards should be composed of progressive men and women and should be free from political restraints. It is an unfortunate thing that in many of our American communities partisan politics play an important role in the selection of school boards, superintendents, and even teachers. Thus far, wherever women have been elected to compose part of the board the situation has been improved and there has been less favoritism and more loyalty to the most important asset of a nation—the physical, mental, and moral welfare of its children.

The more cordial and helpful the relations between city council, school boards, teachers, and parents the more efficient will be the work of all concerned. There should be a time set aside for a parents’ or mothers’ meeting once or twice a month for the discussion of various subjects in order to be mutually helpful. There should also be certain hours for the superintendent or teacher to receive parents and talk over matters which the parents prefer not to discuss in public.

4. The site for a school building should be ideal; on elevated ground, and as far as possible removed from traffic, dust, and noise. The building should be safe, sanitary, well lighted, with good acoustics, and attractive outside as well as inside. Its interior decoration should be educational, esthetic, and inspiring.

Aside from the well known sanitary necessities of any modern public building, the ordinary American windows, which can be opened only to half their extent, should be replaced by French windows, those that slide into the wall, or the kind that turn on a pivot; all of these make possible twice as large an opening as our ordinary windows do. All corners in the rooms should be rounded off, the doors should open outward, and the staircases should be wide and fireproof. The value of object lessons produced on the impressionable mind of the child by beautiful architecture, statues, and pictures is well known to educators. Interior classrooms should be painted with washable oil paints and in colors soothing to eyes and nerves. In interior classrooms the natural or artificial light should be so arranged as to be the most effective and least injurious. Light thrown toward a white or light-colored ceiling seems best for artificial illumination. But not alone should the eye be protected; in our eagerness to save the eyesight of our children we must not neglect their hearing, for good acoustics is as essential to our modern sanitary schools as good light and perfect ventilation.

One or several training schools should form a part of every educational system. If a training school can not be established under the same roof with the general school, it should be easy of access to the latter. There should be rigid State regulations concerning the construction of schoolhouses in order to secure good buildings in unintelligent or illiberal districts and towns.

5. The janitor of a public, parochial, or private school should be a practical sanitarian. Daily cleansing or disinfection of classrooms, when necessary, should be obligatory.

The janitor should at least have a sufficient knowledge of school hygiene and general sanitation to reduce the dangers from dust, bad odors, and bad air to a minimum. He should know how to disinfect and thoroughly clean a classroom. No cleaning nor dusting should ever be done while the children are in the school or while they are leaving the schoolhouse. Dry cleaning except by vacuum cleaner should be considered unsafe. The old-fashioned cleaning with broom and duster is nothing but a displacement of dirt and microorganisms from one place to another. The salary of the majority of janitors is almost invariably higher than that of any teacher, and sometimes as high as that of the principals. Such salaries justify the demand for thorough qualification.

6. The toilet and washing facilities for children should be sanitarily perfect.

Running water, hot and cold if possible, liquid soap, the sanitary paper towel, soft toilet paper, and of course plenty of light and air should be the features of the modern toilet room. The seats of the water closet should be so constructed that the genital organs will not come in contact with the wooden rim of the seat. The water closet seats should not be high, and if they are too high a footstool should be provided to increase the abdominal pressure during the act of defecation. Much of the constipation prevalent in school children would be avoided by this simple means to facilitate the act of defecation and make it more thorough.

7. The rural schools, be they for white or colored children, should not be less sanitary, less well equipped or less well managed than the best public school of a city.

It is a deplorable fact that school hygiene and sanitation in many country districts is virtually unknown. The rural schoolhouse is often inferior in construction and in sanitary equipment to a barn or stable. Much missionary work is needed to make the farmers realize the inestimable assets to a community of healthy children. The Federal Government which now expends millions of dollars for the betterment of animal stock may well divert some of its energy and money to the improvement of rural school hygiene.

Regarding ventilation, toilet, and washing facili-
ties the rural and village schools are even more frequently defectivé than the city schools. It seems as if the good country air was not intended for children attending the village schools.

Wherever, for one reason or another, there are separate schools for colored children, the sanitary and hygienic education of these children should be as rigorous as that in the schools for white children. The hygiene in the homes of the colored working classes is as a rule inferior to that of the white population in the same social stratum, and education through example to the school children is one of the best means to elevate the standard of living of the colored population.

8. The more open air schools we can have, the more outdoor instruction in kindergarten, public schools, and in colleges, the greater will be the physical vigor and strength of the pupils.

Experiments with nontuberculous children have already demonstrated that the pupils attending these open air schools or classes show an average of better attendance, much less sickness, and a better record in their educational attainments. These open air schools have been of particular benefit to children suffering from heart diseases, anemia, and chorea to the underweight and the nervous child. In an excellent article by Elsa Denison, of the New York Bureau of Municipal Research, there appeared a rather appalling diagram of the number of anemic children attending public schools without open air treatment. To show what is still to be done I reproduce this diagram as it is given in Miss Denison’s book. (Fig. 1.)

All children attending open air schools catch colds less easily. This is because there is less chance of propagating infectious colds in the open air schools and the power of resistance is increased in the pupils. So as to encourage the small communities which may fear the expense of such a school, let me say that an open air school does not necessarily mean a new and costly building. Although I described an ideal open air school last year before the Congress on Hygiene and Demography, and my friend, Professor Van Pelt, made the architectural plans for it, showed a model and described the plans and the requisites of such a school, I wish to state that an open air class can be installed in almost any school by taking out part of the wall and replacing it with large windows which will let in air and sunshine in plenty. In the same communication to the Congress, entitled Tuberculosis and Other Diseases in Schools and Colleges: Open Air Schools and Open Air Instructions with Breathing Exercises as Preventive Measures. Professor Van Pelt was good enough to make for me a drawing showing a classroom in an old-fashioned school building which had been altered into an open air room. Providence, which had the first open air class in this country, used an old discarded school building for that purpose. To any community or individual interested in the establishment of an open air school, I will deem it a privilege to send a reprint of the above mentioned article.

9. If we wish effectually to prevent and stamp out tuberculosis in children, the open air school must become the rule, the indoor classroom the exception.

According to the report of the Commissioner of Education there are at this time about 20,000,000 children attending public schools in the United States. Placing the proportion of tuberculosis among them as low as only 5 per cent. would make 1,000,000 tuberculous children who are at this time in urgent need of open air instruction. According to available statistics, and granting even a slight increase since they have been gathered, we can at this time provide open air instructions for hardly 2,000 tuberculous children. The anemic, the nervous, the children suffering from cardiac diseases, who are in equally great need of outdoor instruction, are not included in the five per cent. And yet, how invaluable are these outdoor classes in our warfare against tuberculosis! In his report on the first open air school, Mr. Walter H. Small, at that time superintendent of the Providence schools, has this to say: “The school enrollment in the open air class is varying and the work is necessarily individual. Each does what he can; he is not urged; but he sits in the sun, keeps healthfully busy, drinks in fresh air, and grows stronger physically and more alert mentally. To see the color come into

Fig. 1.—Diagram showing that only 2.7 per cent. of anemic school children have open air classes. The black part shows what is still to be done in the matter of giving open air treatment to anemic children.

Fig. 2.—Diagram showing the results of diagnoses in 1,000 cases.

Fig. 3.—Diagram showing what 1,000 children were doing when brought to the clearing house for mental defectives.

Fig. 4.—Diagram showing that only 3 per cent. of the undernourished school children are having lunches. The black space shows what is still to be done.

KNOFF: VIGOR OF SCHOOL CHILDREN.

Van Pelt, John V.: The Architecture of Open Air Schools, Medical Record, November 1, 1913.

the cheeks and the sparkle into the eyes and to see the emaciated form fill out, convince those close to the work that it pays abundantly."

It goes without saying that teachers and pupils attending the open air school should be warmly clad and the sitting pupil be provided with means to keep his body and particularly his feet warm. In the article mentioned in the preceding paragraph I illustrated Mr. Mann's sitting out bag which is excellent for that purpose. I also illustrated the portable open air school of Jamaica Plains, Boston, suitable for villages and smaller communities, with the children studying outdoors in midwinter.

It is of course essential that a tuberculous child, if it has home lessons, should study and also sleep in fresh, pure air at home, and I presented in the same communication to the Congress on Hygiene and Demography a drawing showing a combination of window tent for sleeping at night and for outdoor studying during the day. A model of such a home study tent which can be converted into a window tent was also exhibited at this congress in connection with my paper, Rest and Exercise for the Tuberculous and the Predisposed Child at School.5

10. If there is not ample room for playgrounds and separate open air classes, the schoolhouse should have a garden, playground, recreation room, and some open air classes on the roof.

Whenever feasible, there should be covered playgrounds so that the children can get the air no matter what the weather conditions. Where land is expensive the roof could be used for this purpose also. In rural communities or smaller towns where land is plentiful and cheap, school gardens should comprise a part of the facilities for outdoor instruction. The roof can, of course, be used to advantage for an open air classroom as has been done in New York and other cities. Providence, as I have said, used a discarded school building and made of it the first open air school in the United States. The schoolroom is large and airy, having windows on three sides. On the south side are five large windows where the wall was removed, reaching from the ceiling nearly to the floor, so arranged with hinges and pulleys that they can be swung inward, practically opening the entire side of the building. These windows are kept open in all weathers except when snow and rain beat in. So far they have never been closed. To temper the air at one end of the room are two stoves; one is for heating simply, the other a cook stove for warming the soapstone and the midforenoon soup. The temperature of the room in winter frequently goes below 40° F. The room is equipped with adjustable desks and chairs on platforms so that they may be moved at will. They have been fitted to the needs of each individual child. The sunshine enters the schoolroom at 9:30 a.m., and remains there all day, and the desks are so moved that while breathing the fresh air the pupils also get the benefit of a sun bath.

A number of suitable roofs of schools and buildings in New York, Chicago, and other cities, and a few discarded ferryboats, have been transformed into open air schools, playgrounds, and roofgardens. Thus it would seem that there is no excuse for any community not having a sufficient number of open air classes and playgrounds for its school children.

11. Let us send the child to the open air or fresh air school before its tonsils or adenoids are enlarged as a result of overwork indoors and of fighting off dust and infection.

The overheated and overdry room and the forcing of dirt and microbe laden air from the street level into the classroom by so called improved artificial ventilation are, I believe, often responsible for the unaccountable infectious colds, adenoids, and enlarged tonsils. Doctor Newsholme, the well known English authority on sanitation, says: "Infectious diseases are caught in the streets only with great difficulty, and this may be described as retail infection, as against the wholesale infection of the schools." The open air schools certainly have the same atmospheric condition as the street, hence the risk of the spread of infection is at a minimum in the open air school and at a maximum in the indoor school. Experience in open air schools has thus far demonstrated that though the term of work is shorter the children attending these schools do better work, are mentally more alert, and happier than the children of the same age attending indoor schools. Howland and Hoolider6 have demonstrated that the remarkable, exhilarating, and tonic effect of the outdoor life is principally due to the increased blood pressure caused by the fresh air.

12. If the indoor classroom must be used, the temperature and moisture should be properly regulated with the aid of the thermometer and the hygrometer and the air kept in motion with the aid of a fan. These three devices should be as essential to the equipment of an indoor classroom as is the blackboard.

It has been scientifically demonstrated that it is rather the excessive moisture and heat and perhaps certain organic products of expiration, which are as yet not known, and not the carbon dioxide that are productive of the discomfort experienced in a badly ventilated, overmoist, overcrowded, and overheated room. With the aid of the thermometer and the hygrometer the temperature and moisture can be regulated and the fan, driven by electricity or water power, will keep the air in motion to counteract the deleterious influence of still, warm air. Experience has proved that we can be perfectly comfortable at a temperature of 65° F. and even a little lower, provided that the percentage of moisture in the air is about sixty. If this moisture falls to thirty or twenty per cent., then the dry throat, dry nose, and dry skin are in evidence. The explanation is simple. The dry air absorbs the moisture from the body and causes discomfort. The drying of mucous membranes in this way lays them open to the invasion of the organisms causing colds, grippe, pneumonia, and tuberculosis. Excessive moisture and heat cause discomfort and lassitude. If the classroom is heated by hot air, a humidifying arrangement can easily be installed on the reg-

---

5Medical Record, November 15, 1913.
ister. Such a humidifier can be made in the following way: Over a pan containing water are suspended a number of pieces of cotton felt, the lower ends reaching the water. The whole is covered by a lattice work box so as to look more sightly. By capillary attraction the water will be drawn up into the felt and the evaporation will impart the desired degree of moisture to the room. What is called lassitude, the lack of energy and ambition to learn, is often nothing else than the effect of confinement for hours at a time in a poorly ventilated, overcrowded classroom.

13. Practical breathing exercises, judiciously taught, should form a part of the daily curriculum.

For lack of space I cannot reproduce here the exercises which I consider most practical, but must refer the reader to another paper read before this congress, entitled, Exercise and Rest for the Tuberculous and Predisposed School Children. It suffices to say that the children who have learned these exercises perform them with pleasure and with regularity, and where careful statistics have been kept (as, for example, in one of the Paris schools), it was shown that chest expansion, general well-being, and strength increased, and that there were fewer absences from school on account of sickness after the respiratory exercises were inaugurated than during the same period of time prior to their introduction.

14. Outdoor singing, outdoor recitation, the training of the voice to speak and intone properly, botanical and geological excursions, visits to zoological gardens and aquariums, and practical lessons in horticulture or in farming, should be introduced as often as the curriculum will permit.

Experiments in the German army have shown that singing in the open air on marches and in camp improves chest expansion, has a general benefit on the heart and circulation, and makes the individual less susceptible to laryngitis and pharyngitis. Recitations in the open air are of equal benefit to the respiratory tract and will strengthen voice and lungs and benefit the general system. One of the most progressive and scientifically managed schools in New York city, the Ethical Culture School, makes it a point to have frequent excursions into the outlying country during the autumn and spring for the purpose of securing pure air and country environment. Very justly do the authorities of this school announce in their reports that such excursions offer unusual possibilities in the way of recreation and nature study, and provide concrete material for geography, arithmetic, and all school work.

The celebrated Bryn Mawr College for girls has recently established a preparatory school offering a curriculum of seven years of study in the open air. This experiment will be watched with interest by all educators, physicians, and sanitarians. At no time in life is there more opportunity for training the voice to speak properly than during the school age, and particularly at the time when the girl develops into a woman and the boy's voice changes to that of a man. This voice culture is to my mind a much neglected study in the majority of our public schools. There is no field in the activities of life of man or woman where a well modulated voice will not be an addition to the armamentarium in life's battles. Let me quote here in relation to this from the writings of a well known physician, Dr. T. D. Crothers, of Hartford, Conn.:

"The thoughts and impulses of the mind should be expressed in the very best way and not in the coarsest, harshest manner. The voice should be trained before the intellect, for if this is neglected, the intelligence can never be presented with the same effectiveness." It certainly seems to me that here is a field for a very useful innovation in the curriculum of our schools.

15. Inculcate the love for open air life into the child at school and it will become a fresh air apostle at home.

Those working in tuberculosis among the poor well know what an invaluable help in improving the home hygiene are the children who are obliged to attend tuberculosis clinics. They will insist on the open window in their homes, and cleanliness and freedom from dust will become features where foul air and dust were common prior to the education of these youngsters in sanitation. Leaflets instructing children in simple sanitation and hygiene should be taken home so that the parents may have an opportunity to read and study them and benefit by the instructions contained therein. In this and in many other respects the school can, and in fact does often, reform the home.

16. If desirable, let the child between four and six attend a kindergarten; but between the ages of six and eight let it attend a playschool devoted principally to the physical and moral development.

For the kindergarten as well as for the playschool let us accept what is good and practicable from the now well known Montessori method and particularly encourage initiative. Let the child in the kindergarten work when it wishes to work, rest when it wishes to rest, play when it wishes to play. In the playschool, which should always be an open air school, character building and physical development should be the principal objects. Perhaps at no age in the child's life will the physical as well as the moral development yield good results so readily in response to proper training as between the ages of six and eight. Outdoor games and breathing exercises will develop the child's chest to render it practically immune to tuberculosis. It is at this period of physical development that the bony frame of the chest yields most readily to expansion. During the years from six to eight the child needs but very little real school training; one lesson in the forenoon and one in the afternoon, each of three quarters of an hour duration, should suffice.

17. For the average child the age of eight is ample time to enter a public school. The child will be better equipped mentally and physically at that age to stand the strain of continued school life than had it been sent at the age of six.
In a few families where it was my privilege to act as family physician and counsellor, this advice has been followed, particularly with the children of tuberculous parents. The results have been surprising. Those children who entered school at the age of eight without exception caught up with their fellow students who had attended school two years longer. In after life most of these children have proved physically and mentally above the average.

18. So long as we permit child labor in factory, workshop, cannery, field, mine, or at home, so long will we have physically, mentally, and morally defective citizens.

The anatomical and physiological development of the child will always be impaired by physical strain imposed upon it by cruel child labor. The delicate nervous system of the growing child, as well as its impressionable mind, will invariably suffer from the humdrum existence and the social environments it is exposed to when working in factory, cannery, or mine, or confined at home in constant toil. There is no excuse for child labor. I go so far as to say it would pay the State to subsidize the parents of a large family when, upon investigation, it has been shown that they cannot support themselves properly without the earnings of the children. In Miss Denison's book, from which I have already quoted in the chapter on antichild labor and procompulsory education, the author very pertinently says: "When our schools shall reach out and give practical help to every child, the problem of child labor will largely be solved."

19. No State government of this great Union believing in the equality of men and the principles of the Declaration of Independence upon which this republic is founded, has a right to allow child labor to exist anywhere within its borders.

Let these governments which, to their shame it must be said, still allow child labor to exist, listen to the Declaration of Independence of these toiling children of America who are forced into the mines, factories, and workshops like slaves and not like children of free men. Through their spokesman, Mr. A. L. McKelway, of the National Child Labor Committee, they say:

WHEREAS, We, Children of America, are declared to have been born free and equal, and
WHEREAS, We are yet in bondage in this land of the free; are forced to toil the long day or the long night with no control over the conditions of labor, as to health or safety or hours or wages, and with no rights to the rewards of our service, therefore be it

Resolved, I, That childhood is endowed with certain inherent and inalienable rights, among which are freedom from toil for daily bread; the right to play and to dream; the right to the normal sleep of the night season; the right to an education, that we may have equality of opportunity for developing all that is in us of mind and heart. And be it

Resolved, II, That we declare ourselves to be helpless and dependent; that we are and of right ought to be dependent, and that we hereby present the appeal of our helplessness that we may be protected in the enjoyment of the rights of childhood. And be it

Resolved, III, That we demand the restoration of our rights by the abolition of child labor in America.

20. The well known methods of daily medical inspection of all school children to exclude those afflicted with acute and chronic infections and general and local diseases should be supplemented by a thorough physical and mental examination of every pupil by the school physician on admission, and by annual or semianual reexaminations for tuberculosis, heart disease, insidious nervous affections, etc. A careful record of the physical and mental condition of the child should be kept and the result of each physical and mental examination recorded.

It is only by such examination and periodical reexaminations that incipient tuberculosis or in- cipient disease of the heart or the nervous system, or surgical or dental affections can be discovered; and only by the treatment of children thus afflicted at the right time, and in the right place, can we hope to restore them to useful citizenship. Supple- mentally the record of the physical condition of the child at the time of its entrance into the school should be a statement of what can be learned con- cerning the child's antecedents. Whenever there is occasion the teacher should register in this record anything of importance bearing on the physical and mental development of the child. Such a record, very simply called a biographical chart, and I believe first suggested by Seguin, Sergi, and Montessori, is, if I am correctly informed, already kept in a few American schools. It must be evident that by consult- ing such a record, teacher, physician, and parents will have an invaluable guide for the manage- ment of any child physically or mentally not up to the normal.

21. Teachers and all school employees who come in close contact with the children should likewise be examined on admission and submit to periodical re- examination. Every large school should have a trained nurse in attendance during sessions.

The tuberculous teacher and tuberculous janitor, for example, may become a menace to the pupils, and these examinations are also in the interest of employees of the public school, so that in the event of their being afflicted with tuberculosis or other diseases, the right treatment may be instituted in time to effect a cure.

No large public school, particularly in the greater cities, should be without the constant attendance of a trained nurse during school hours. This nurse should have the addresses of the number of physicians who can, in case of need, be called at once. By mutual agreement among the physicians it could be arranged that one of them would always be within reach during school sessions. By such a provision many a serious disease or accident may be averted or its consequences greatly minimized.

22. The kindergarten, playschool, private, or parochial schools, or evening classes should be as carefully watched and supervised as the public day schools.

Contagious and communicable children's diseases,
including the disease known as the simple cold, which is often as infectious as others and sometimes more so, are most easily propagated in the indoor kindergarten or private school. Children should, of course, be excluded while the contagiousness of the disease lasts. No license should be granted to a private kindergarten or other teaching institution if its managers will not submit to, and abide by the sanitary regulations in vogue for the prevention of disease in pupils of the public schools.

In dealing with the children of the poor one cannot always expect the tidiest and cleanest clothing, nor the dress without an occasional hole. Sometimes the garments of the little ones are decidedly dirty, and aside from that I believe germs of infectious disease may lurk in them from previous diseases of the wearer. Sometimes a child wears the garments inherited from his older brother or sister, and these garments too may have become infected. To obviate this source of infection, I would suggest that gingham aprons be furnished to these children while attending the kindergarten. There should be enough of these aprons so that clean ones can always be on hand, and they should cover the child's clothing entirely. The cost of these is but little, and I firmly believe it would pay in either the municipality or philanthropic institutions would undertake the provision of such protective garments. I have tried this experiment in a settlement vacation home in which I am interested, with most satisfactory and also rather pleasing esthetic results.

If luncheon is ever indicated it certainly is in the kind of kindergartens just referred to. From an interesting article entitled Hygiene and the Kindergarten, by Miss Wanda Hilborn, in charge of the Bloomingdale Guild Kindergarten, New York, I quote the following to substantiate the need of luncheons: "But most of the little tenement children are pale, and lack of nourishment, especially breakfast, looms very black on the kindergarten horizon; so at eleven a large cup of hot milk and a graham cracker is very acceptable indeed."

To the best of my knowledge no attempt has ever been made to eliminate from the evening classes, located in public schools, individuals afflicted with disease who would never be admitted to day schools. The classrooms occupied by pupils of the evening classes are very often used the next day by smaller children. In not a few instances these classrooms are used again without having undergone even a thorough ventilation, not to say disinfection. Classrooms designated for evening instructions should be provided with the best possible lighting system and be thoroughly ventilated before and after occupation by the evening classes.

23. Throughout all the grades from kindergarten to college, pupils should be discouraged from kissing each other, because of the danger of becoming infected with disease through this practice.

It is well known that tuberculosis can be transmitted by the kiss from a tuberculous individual: the same holds good of syphilis. Even the germs of pneumonia and grippe or the common cold are known to have been transmitted by a kiss and to be the cause of disease in the recipient of this embrace. The pneumococcus, that is to say, the germ of pneumonia, may be in the mouth of the adult even if he is in perfect health, but transmitted to the delicate and susceptible respiratory system of the child may cause pneumonia. Diphtheria may likewise be transmitted from one person to another through the kiss. Children should be taught not to allow any fellow pupil or stranger to kiss them, and the parents and relatives should form the habit of only kissing the little ones on the cheek—never on the mouth.

24. The tuberculous or predisposed, the mentally defective, delinquent, or backward children should have separate schools, preferably in connection with a sanatorium, or should at least be placed in separate classes or schools located in the most sanitary region of the city.

The necessity of separating the abnormal from the normal child and also of grading it according to its intelligence, has been well demonstrated by a careful analysis of the results of the examination of 1,000 children who were brought to the clinic of the Post-Graduate Medical School and Hospital at Twentieth Street and Second Avenue, New York city. This clinic is under the direction of Dr. Max Schlapp, and is serving as a clearing house for New York's mentally defective children. The accompanying charts (Figs. 2 and 3), published by Dr. Louis E. Bisch, one of Doctor Schlapp's associates, show the necessity of such a clearing house in every community of any size. With the aid of such an institution a great deal of prophylactic and curative work can be accomplished among these unfortunate children.

The child afflicted with pulmonary tuberculosis must, of course, also be specially trained and watched, while the child with a nonopen tuberculous joint disease may safely associate with normal children. Experience has, however, demonstrated that children suffering with local tuberculosis more quickly and more surely get cured in special sanatoria in seacoast or mountain climates. School instruction for these tuberculous children should, of course, also be provided for. Public school teachers who have been unfortunate enough to contract tuberculosis would here find opportunity to continue work and become cured at the same time.

Because there are in the United States at this time at least one million tuberculous school children, or school children strongly predisposed to tuberculosis, and existing open air schools and sanatoria have only accommodation for about two thousand, I intend to present before this congress resolutions petitioning the United States government to place at the disposal of the various States of the Union as many of the discarded battleships and cruisers as possible to be anchored according to their size in rivers or at the seashore, and to be used by the respective communities for open air schools, preventoria, or sanatorium schools for children.

These resolutions were unanimously passed at the final meeting of the congress on August 29, 1913. Knopf: Discarded Battleships to Be Used as Sanatoria and Open Air Schools, New York Medical Journal, September 13, 1913.
shall also ask this congress to express its appreciation to the Italian government of the example it has given by consecrating three of its discarded battleships to the combating of tuberculosis. In justice to those States which by reason of their location cannot make use of discarded battleships, I will suggest that a nominal sum be paid for these vessels by the States desiring them and the money proportionately turned over to inland States for the establishment and equipment of open air schools, preventoria, sanatoria, or hospitals for consumptives. By such a policy the greatest possible good to the greatest number of American citizens afflicted with tuberculosis will be attained.

25. A goodly number of the seemingly delinquent, defective, and backward children are of syphilitic origin, and before classing them permanently with the defective, a Wassermann test should be applied, and if positive, antisyphilitic treatment inaugurated.

Many of these unfortunate children may thus be successfully restored to physical and mental vigor. It goes without saying that the utmost tact on the part of the school physician and school authorities should be exercised in dealing with the parents of such defective, delinquent, and backward children.

26. The hopelessly feebleminded and defective child should be rendered sterile before puberty, or at least permanently segregated.

We are making every effort to prolong the life of our fellow being, no matter how seriously he is afflicted physically and mentally, and anything intended to shorten the life of the most useless is considered inhuman. On the other hand, society must protect itself. The restriction of marriage laws so that there may be no matrimonial union of the feebleminded is of relatively little avail. Clark and Stowell very justly say concerning this: “Aside from the fact that the unfit often have little need and infrequently invoke the right of marriage license to propagate, this latter rational but utopian scheme (restriction of marriage) interests society but little at present. Love in its protan form not only laughs at locksmiths, but gives little heed to social rules and customs running counter to its desires.” Eugenics must be our first resort, sterilization our second, and the questionable method of segregation only our third resource in our endeavors to prevent the mating of the unfit. Yet in the meantime, until our statesmen will have seen the necessity of such legislation, the hopelessly defective and feebleminded child should be segregated in State institutions for life and not, as is now so frequently done, merged again into the general population after the schools get through with him or her as a pupil.

27. Health lessons and simple instructions in the prevention of disease, such as tuberculosis, for example, can easily be imparted to even the youngest child. The same holds good for many other diseases and can help in the education of parents and children alike.

Let me, as an example, quote from one of my previous articles\(^{13}\) the following rules for school children, which, I am happy to say, have been distributed in a number of schools and which have proved a very efficient help in the prevention of tuberculosis:

**SIMPLE RULES FOR SCHOOL CHILDREN TO PREVENT TUBERCULOSIS.**

Every child and adult can help to fight consumption. School children can be helped by complying with the following rules:

- Do not spit except in a spitoon, a piece of cloth, or a handkerchief used for that purpose alone. On your return home have the cloth burned by your mother, or the handkerchief put into water until ready for the wash.
- Never spit on the floor, slate, playground, or sidewalk.
- Do not put your fingers into your mouth.
- Do not pick your nose or wipe it on your hand or sleeve.
- Do not wet your fingers in your mouth when turning the leaves of books.
- Do not put pencils in your mouth or wet them with your lips.
- Do not hold money in your mouth.
- Do not put pins in your mouth.
- Do not put anything in your mouth except food and drink.
- Do not swap apple cores, candy, chewing gum, half-eaten food, whistles, bean blowers, or anything that is put in the mouth.
- Peel or wash your fruit before eating it.
- Never sneeze or cough in a person’s face. Turn your face to one side or hold a handkerchief before your mouth.
- Keep your face, hands, and fingernails clean. Wash your hands with soap and water before each meal.
- When you don’t feel well, have cut yourself, or have been hurt by others, do not be afraid to report to the teacher.
- Keep yourself just as clean at home as you do at school.
- Clean your teeth with toothbrush and water, if possible after each meal; but at least on getting up in the morning and on going to bed at night.
- Do not kiss any one on the mouth, nor allow anybody to kiss you.
- Learn to love fresh air and learn to breathe deeply, and do it often.

Equally terse rules can be given to children to make them help in the combating of diseases propagated by flies and mosquitoes, or through infected milk or water. For older children preventograms, such for example as the following,\(^{12}\) will greatly help in the teaching and practice of general hygiene:

- Kill flies, save lives.
- Uphold the hands of those who would prevent disease.
- Communicable diseases come only from the germs of those diseases.
- Kill or render harmless the germs and you will prevent the spread.

Moderate, not excessive exercise will build up a wall of resistance against bodily foes. Drink plenty of fresh water. It is the best drink for coolness, comfort, and health.

Regulate your diet to suit the season. Meats and fats—heat producers—for the cold weather; fruits and vegetables for hot weather.

Hygienic exhibits, particularly tuberculosis exhibits, open to the parents as well as to the children, will also be valuable auxiliants.

28. Lessons in mental alertness, in what to do in hours of danger, such as the event of fire in school or at home or a panic from whatever cause, and instruction in first aid to the injured, are to my mind as essential as any health lessons.
December 6, 1913]

GWATHMEY: OIL-ETHER ANESTHESIA.

1101

Let the child know how to behave in crowded streets, how to avoid vehicles, even what to do in case of accidents to others, also what to do in case of fire, drowning, or other catastrophe. An occasional lesson in fire prevention given to the pupils, preferably by the fire chief of the town, would probably result in the reduction of the many fires in our American communities. Many a serious accident may thus be avoided, or its consequences minimized. A child should know how to get off a street car so as not to fall. It should be taught that cleanliness will minimize the danger from wounds or bruises. From a very interesting article by Dr. Charles A. Kinech, of New York, I beg leave to quote as follows: "The boy at ten or eleven realizes that he has a neighbor and he wants to do something for that neighbor. His sufferings appeal to the boy's sympathies. Then also he is able to understand the mechanism of the human body and has acquired a certain amount of dexterity in the use of his hands and members. And he has attained a measure of stature and strength that makes him efficient in rendering prompt aid to the injured. Of girls, about the same things can be said. They are more capable of serious altruistic thought after the thirteenth year than in their childhood days. And by that physical and mental development better able to comprehend and apply the principles of first aid." It goes without saying that there should be regular fire drills in every public or private school, and boys and girls should know how to render first aid in case of drowning.

(To be concluded.)

OIL-ETHER ANESTHESIA.*

By J. T. Gwathmey, M. D.,

New York.

Oil-ether colonic anesthesia is an evolution from intravenous anesthesia. In developing the technic, however, full advantage has been taken of all that has been written on rectal anesthesia, as revived by Cunningham, of Boston, and continued by Sutton, of Kansas City, when an interne at Roosevelt Hospital.

The animal work under the direction of Professor Wallace in the pharmacological laboratory of New York University and Bellevue Medical College has already been reported.

In a paper read before the International Medical Congress in London, I strongly recommended Car- ron oil as the vehicle for the ether, because this oil parts with the ether in about one fourth of the time of the other oils; it also seems to be less irritating to the mucous membrane. An unfortunate experience in one of the hospitals, however, compelled me to discard Carron oil entirely. The apothecary of the institution attempted to make this mixture with olive oil instead of linseed oil, but as linseed oil is the only one that mixes with lime water, when ether was added to the compound the oil separated immediately, with the result that about 100 c. c. of pure ether was introduced into the rectum before the mistake was discovered. Olive oil alone was then used with the ether, and the anesthesia was successfully completed. The operation in this case was a hysterectomy, and the relaxation was perfect, but the patient suffered considerable pain afterward and recovered slowly, although completely, from the effects of the anesthesia. Since this time I have used the olive oil exclusively, the resulting anesthesias not being followed in any case by diarrhea or bloody stools.

The cases in which olive oil was used seemed to have less nausea and vomiting than those in which other oils were used. This verifies the work of Graham, relative to restoration of the opsonic index by the absorption of olive oil into the system after operation. (Graham, Journal of the American Medical Association, March 26, 1910, p. 1043.)

The advantages claimed for this method of anesthesia over other methods are:

1. The element of apprehension and fear caused by placing a mask over the face in inhalation anesthesia is avoided.

2. No expensive apparatus is required.

3. The after effects of the anesthetic are reduced to a minimum.

4. A more complete relaxation is secured than with any other known method of administration.

5. The limits of safety are widely extended, compared with other methods.

6. A more even plane of surgical anesthesia is automatically maintained than is possible by any inhalation method—unless administered by a skilled anesthetist using a perfected apparatus.

These propositions have been demonstrated in about one hundred cases, the ages of the patients ranging from four to seventy-one years. In all of these cases the operations have been witnessed by members of the profession, in one instance forty physicians and surgeons being present. In most of these cases careful blood and urine analyses were made before and after the operation. The blood pressure was taken during the operation. Some of the patients were also carefully examined with the proctoscope, to note if any inflammatory disturbances followed the anesthetic. None of these examinations showed any contraindications to the method.

Patients who had been previously anesthetized by other methods and who were capable of making an intelligent comparison, expressed themselves most enthusiastically in favor of oil-ether. In two instances of delayed necessary operations, this form of anesthesia so appealed to the patients that all objections were overcome.

CASE REPORTS.

The following cases have been selected as illustrating the dangers to be avoided and the doses to be employed:

Case I. Boy, aged ten years; operation for hydrocele, and circumcision. One twelfth grain sulphate of morphine was given hypodermically thirty minutes before the operation, and a five grain chloretone suppository at the same time; between 75 and 100 c. c. of a 75 per cent. mixture was introduced very slowly, the patient falling asleep before the full amount was introduced, sleeping quietly through the operation, and making an uneventful recovery.

In children of four to eight years of age, a fifty or fifty-five per cent. solution of ether in olive oil has been easily retained, without any preliminary

*Kinech: Teaching of First Aid in Schools, New York.

*Read before the New York Society of Anesthetists, Thursday, November 20, 1913.
medication, and has been followed by satisfactory anesthesia in ten to twenty minutes. The low percentage absorbed by children is contrary to our laboratory experiments, as the oil does not part with the ether in fifty per cent. solutions in a test tube placed in a water bath at the temperature of the body. The difference in the power of absorption from the lower bowel in children and adults would satisfactorily explain this. In adults, eight ounces of ether, with an equal amount of oil, was placed in the rectum with no anesthetic effect whatever.

Case II. In a girl, nine years of age, 100 c.c. of a 75 per cent. solution was given with no preliminary medication. The child complained slightly as the mixture was administered. The operation was for adenoids and enlarged tonsils. The relaxation was perfect, and the child was able to leave the hospital five hours after the operation.

Several other cases of different operations on children have been reported by different surgeons, who expressed themselves unqualifiedly in favor of this method of anesthesia.

Case III. On November 18th, a woman, aged thirty-eight years, weight 125 pounds, was operated upon at the Presbyterian Hospital by Dr. Forber Hawkes for carcinoma of the breast. The patient was given one sixth of a grain of morphine, and one hundredth of a grain of atropine hypodermically; five grains of chloroethane, dissolved in two drams of ether, and mixed with two drams of oil. The suppository was introduced into the rectum thirty minutes before the operation. Eight ounces of a 75 per cent. mixture was introduced into the rectum in six minutes' time. The patient was in surgical anesthesia four minutes after the total mixture had been introduced. Three ounces were drawn off during the operation, as the patient seemed to be too deeply narcotized. The resultant anesthesia was perfect in every respect, the patient breathing quietly as in natural sleep during the entire time of the operation. A perfect uneventful recovery with no nausea or vomiting followed. Blood and urine analyses proved negative.

Case IV. On November 17th, a similar case was operated in by Doctor Cantle at the New Rochelle Hospital, with equally gratifying results. In this instance, the patient was given one grain of morphine and one hundredth of a grain of atropine hypodermically, thirty minutes before the operation. No suppository was used, and patient complained slightly of discomfort in the rectum as the mixture was introduced.

Case V. Operation for abdominal hernia by Doctor Bodine at the New York Polytechnic Hospital: The patient, a woman, aged thirty-seven years, weight about 150 pounds, was given one quarter grain of morphine and one hundred and fifty grain of atropine thirty minutes before the operation. At the same time a solution containing to grains of chloroethane and 4 drams of ether with an equal amount of olive oil was introduced into the rectum. Just before the operation 75 per cent. mixture of oil and ether was given to the patient in bed. She sank into deep surgical narcosis before the full amount (8 ounces) was introduced. A slight cyanosis indicated an overdose, therefore three and a half ounces of the mixture was drawn off, as the patient was placed upon the operating table. The relaxation in this instance was perfect; pulse and respiration were about normal. The patient slept for six hours after completion of the operation and woke without nausea or vomiting, in a perfectly satisfactory state in every respect.

The two following cases show that watchfulness must be exercised at all times, as in other anesthetics, and that the chief danger connected with this method is respiratory arrest.

Case VI. A woman weighing less than one hundred pounds, about thirty years of age, was operated upon for pelvic cellulitis. She was given one quarter grain of morphine and one hundred and fifty grain of atropine hypodermically, and a suppository containing 20 grains of chloroethane, as preliminary medication. Eight ounces of a 75 per cent. solution of ether in oil was given after the anesthetic. This showed no evidence of overdosage of preliminary medication, also of the anesthetic. Respiratory arrest occurred a few minutes after she was placed upon the operating table. Artificial respiration, stretching of the sphincter, and the intravenous introduction of 1,000 c.c. of normal saline were employed. A bag containing a small amount of carbon dioxide was then placed over her face, whereupon respiration recommenced immediately.

During the time of this respiratory arrest, which, according to the operating nurse, lasted eight minutes, the pulse was full, regular, and approximately normal. The color of the lips and tongue was good. The operation was satisfactorily performed, and the patient was returned to bed. An uneventful recovery is recorded in this instance, with no nausea or other effects.

Case VII. Private patient; excision of the tongue, floor of the mouth, and glands of the neck. On account of adhesions and abnormalities resulting from a cancerous growth, this operation lasted nearly three hours. The patient was a man of about forty-seven years, weighing about 160 pounds. He was given one quarter grain of morphine with one hundred and fifty grain of atropine hypodermically, half an hour before the operation, and ten grains of chloroethane in a suppository at the same time. Eight ounces of a 75 per cent. mixture of oil and ether was administered. The patient dropped to sleep almost immediately. At the end of one hour the pulse was full and regular, but there was stertor which perceptibly increased until respiration ceased for three minutes. The rectum was washed out with cold water, and as much as possible of the mixture was withdrawn. Respiration recommenced without anything else being done, and the operation was commenced and completed without further interruption. When the patient was returned to bed the pulse was 72 and the respiration normal. This patient also made an uneventful recovery, with no nausea or diarrhea following.

An inhalation anesthetic would have undoubtedly increased the engorgement and congestion usually following such cases. This case is given to illustrate a peculiar phase of the physiology of this particular method. In all oil-ether anesthetics the respiration should be quiet and easy, as in sleep. If stertor occurs, and the reflexes become dull (especially the lid reflex), it is an indication of an overdose and the rectum should be immediately washed out and one or two ounces of oil introduced.

No deaths can properly be credited to this method, although one patient succumbed within twenty-four hours, operation being completed without further interruption. The patient was conscious and had fully recovered from the anesthetic. The coroner's inquest revealed the fact that every organ in the body was diseased, and that a vegetating growth completely obstructed one of the coronary arteries. In the opinion of the surgeon and the coroner, these conditions fully accounted for the death.

These three cases are cited with the idea of safeguarding the method, and to show that care and judgment must be exercised with regard to the preliminary medication and to the amount and percentages of the anesthetic used.

1In the author's opinion this freedom from discomfort was entirely accounted for by the administration of the chloroethane.
CASES VIII, IX. At the commencement of the series, two patients were anesthetized at Roosevelt Hospital. In each instance, unpleasant symptoms occurred on the introduction of the anesthetic, and in each a supplementary anesthetic was required. These patients received the anesthetic in the dorsal position, which has since been abandoned.

With improvements in technic no untoward incidents or failures have been recorded.

PHYSIOLOGY.
The physiology of oil-ether colonic anesthesia is interesting and must be understood in order to administer the anesthetic intelligently. The breathing, in all instances, is perfectly normal. If stertor commences, it is an indication of an unnecessary deepening of the anesthesia. Cyanosis should not occur; if present at any time, it indicates an unnecessary depth of anesthesia. The reflexes are quite active, especially the lid reflex. The pulse is normal, or only slightly accelerated, depending upon the preliminary medication. The face is never flushed, as with ether given by inhalation.

All of the foregoing conditions are the result of the method of the introduction of the anesthetic. As the ether separates from the oil after its introduction, it assumes the form of a gas and is taken up by the blood. It then passes through the lungs, where a part is excreted and lost; the remainder is immediately resorbed, and thence reaches the brain. As a large quantity of the vapor is lost by exhalation, the brain is never so deeply narcotized as when the anesthetic is administered by inhalation. This probably accounts for the wide latitude of safety provided by this method. With no other anesthetic or method of administration would it be possible to have a patient's respiration cease for eight minutes and recommence, as in one of the cases cited in this paper. In inhalation methods, the higher centres of the brain are first affected. The first symptom noticed by patients undergoing anesthesia by the oil-ether colonic method is loss of sensation in the lower extremities, showing a senso-motor paralysis, first of the extremities, the higher centres of the brain being the last affected. This observation seems to be verified by the manner in which patients come out from the influence of the oil-ether anesthesia. Consciousness is regained long before the sensations of pain are manifested. This last observation opens up a wide field for investigation and research, since we now know that ether can be introduced into the system without its nauseating effects being manifested. In a fifty or sixty per cent. solution it may be administered for the relief of pain, just as we would use a hypodermic injection of morphia, with the same degree of assurance and without the possibility of an injurious habit being acquired.

INDICATIONS.
The method is especially indicated in bronchoscopic work and in operations upon the head and trunk; also in cases of Graves's disease and similar conditions, where the element of fear is a dominant factor. It has been demonstrated conclusively that we can administer it with confidence to those patients who have suffered much nausea and vomiting from the previous administration of ether anesthesia. It may be positively asserted that the ether is not so irritating when given in this way as by the usual inhalation method. It has been given to a consumptive having hemorrhages from the lungs, at irregular intervals, with no deleterious effects.

CONTRAINDICATIONS.
If the facts just stated are borne in mind to modify our conclusions, we may state that it would be contraindicated in most cases where ether is contraindicated; also in colitis, hemorrhoids, fistula in ano, or other pathological conditions of the lower bowel. Even where no pathological condition exists, if the patient complains upon its introduction, this would also be a contraindication to the method.

COMPARISON WITH OTHER METHODS.
It is not to be expected that this method will be generally adopted until at least one thousand cases are collected and carefully tabulated to show the results. But this is only a question of time; those who are wedded to either spinal or intravenous anesthesia will welcome oil-ether as fulfilling all the requirements of these methods without incurring the possibilities of infection or other serious trouble. The combined method, as I have outlined it, will also attract those who wish for such simplicity of administration and directness as is afforded by the drop method of ether anesthesia. Nitrous oxide and oxygen can be administered in a much greater number of cases with fewer possibilities of discomfort when used in combination with one half of the oil-ether mixture required for full anesthesia. The relaxation obtained is more satisfactory than with nitrous oxide-oxygen and ether given by inhalation. For endotracheal anesthesia, in addition to the oil-ether in the rectum, any pump that will deliver sufficient air to maintain the necessary positive pressure in the lungs will be the only apparatus needed.

I particularly wish to emphasize at this time, however, that the combination of oil and ether can be safely introduced into the system and that the anesthetic is always under the control of the operator. The reasons for this are:
1. The anesthesia is automatically safeguarded by the gradual and equal absorption of the ether from the colon and at the same time its rapid evaporation from the lungs.
2. The affinity of the oil and ether for each other.

DEVELOPMENT OF METHODS OF ADMINISTRATION.
In a former paper I made the statement that "to a practitioner compelled to work alone, this method would be of inestimable benefit." From experience since gained in a number of cases I find that this opinion requires some modification. For a practitioner so circumstanced, it would be safer to use a fifty-five to sixty-five per cent. solution of ether and oil, allow fifteen or twenty minutes for the mixture to have its full physiological effect, and then supplement this, if necessary, with a few drops of ether on a mask. This would be better than getting the patient deeply under the anesthetic with a seventy-five per cent. solution, with the possibility of having to withdraw some of the mixture if the patient was too deeply narcotized. This combined method would also apply to hospital internes and others who have not had extensive experience with anesthetics. To any one compelled by circumstances to place the narcosis in the hands of a lay-
man or one unskilled in anesthesia, this combined method would be safer than to allow the anesthetic to be given by inhalation exclusively, as heretofore.

In using the oil-ether method alone, the anesthetist must have well in mind the physiology, as outlined above, in order to avoid mistakes. The following rough outline will serve as an aid in deciding upon the percentages and amounts to be used in given cases.

For children under six years of age, a fifty per cent. solution should be employed, allowing one ounce of the mixture for every twenty pounds of body weight. This mixture is nonirritating, and no preliminary medication is required.

For patients from six to twelve years of age, use a fifty-five to sixty-five per cent. solution, without preliminary medication, keeping the patient quiet, and allowing twenty to thirty minutes for the full effect. Allow one ounce for every twenty pounds of body weight, as before.

For patients from twelve to fifteen years of age, use the same percentages and amounts, with possibly the addition of one tenth grain of morphine and one two hundredths of a grain of atropine, given hypodermically as a preliminary.

From fifteen years upward, a seventy-five per cent. mixture is employed, the amount and preliminary medication varying with the size and general condition of the patient and the same rule being followed as to quantity, that is, one ounce for every twenty pounds of body weight. Thus we see, for an adult weighing about 160 pounds, eight ounces would be required. This represents the usual dose for the average patient.

The administration of any preliminary medication will always vary with this, as with other methods of administration, depending largely upon the opinion of the surgeon or anesthetist. For adults, I usually employ five grains of chloroform, dissolved in two drams of ether and mixed with an equal amount of olive oil, given per rectum thirty minutes before the operation. In addition to this, one eighth to one quarter grain of morphine, with one hundredth grain of atropine is given hypodermically at the same time—the larger doses being given only to athletes and alcoholics.

**PREPARATION OF PATIENT.**

The patient should receive the usual medication as for any operation, care being taken to avoid purging. In addition, the colon should be thoroughly irrigated until the return is clear. A rest in bed of two hours or more before the administration of the preliminary medication is required.

**APPARATUS.**

The apparatus required is very simple, consisting of a small catheter and funnel into which to pour the mixture; two small rectal catheters inserted side by side to withdraw the fluid and irrigate the colon; and a towel which is placed over the face of the patient from time to time, to prevent the dilution of the anesthetic in the air passages. When the patient is satisfactorily narcotized, the towel is withdrawn.

**TECHNIC OF ADMINISTRATION.**

The mixture (two ounces of olive oil and six ounces of ether) is given with the patient in bed on the left side, in the Sim's position, a convenient lifter having previously been placed under him. It is not always necessary that he should know that an anesthetic is being administered. A small catheter, well lubricated, is then inserted three to four inches within the rectum; to this catheter a funnel is attached. The mixture should be poured slowly into the funnel, at least five minutes being consumed in administering eight ounces, the usual amount required. It is best not to withdraw the tube immediately, but to wait until the patient is partly unconscious and the muscles are relaxed. From five to twenty minutes (according to the percentage used) should be allowed for the anesthetic to take effect, before the patient is moved. The patient should then be lifted gently on a stretcher and carried to the operating room. The anesthetist at this time should see that a clear airway is maintained when necessary, by placing a finger under the symphysis of the lower jaw. If the patient shows signs of approaching cyanosis, loss of lid reflex, stertor, or embarrassed respiration of any kind, two or three ounces of the mixture should be withdrawn by the small rectal tube already mentioned, placed four to six inches up the rectum. If the breathing is easy and regular, with the reflexes active, the patient will be found to be relaxed and in surgical narcosis as far as the operation is concerned.

At the end of the operation, the two small rectal tubes already mentioned should be placed in position, as high up the colon as convenient without traumatism, and cold water soapsuds injected into one tube and drawn off through the other; two to four ounces of olive oil should then be introduced into the rectum and the tubes withdrawn. The patient should be gently returned to bed, with as little jolting or handling as possible, the room should be darkened, and free ventilation secured.

In some of the cases mentioned novocaine was injected locally at the site of the operation after the patient came on the operating table. In other cases no local anesthetic was used. Where a local anesthetic is used at the site of the operation, and the ether is administered by the oil-ether rectal method of injecting, as I have outlined, every principle of anocri association as enunciated by Crile will be fulfilled, and the patient awakes quietly, without nausea, vomiting, or pain, the analgesia continuing for some time after consciousness is restored.

40 East Forty-first Street.

**CANCER OF THE UTERUS AND THE AMERICAN SOCIETY FOR THE CONTROL OF CANCER.**

By LE ROY BROUN, M.D.,
New York,
Surgeon to the Women's Hospital.

The American Gynecological Society selected to be specially considered during its annual meeting of 1912 the subject of cancer of the uterus. The papers submitted by its fellows covered years of...
devoted and highly skilled surgical efforts. The one prominent fact brought out during this consideration was that few women with cancer of the uterus seek aid during the earliest stages of the disease. This knowledge was common to all, yet it required the united expression of the many to carry the weight that was needed for a common action.

The result of the discussions was that a committee was appointed and instructed to consider the best means of educating women and impressing upon all the absolute necessity of the early recognition and treatment of cancer. They were instructed to present their conclusions to the society at its meeting in 1913.

This committee, after months of investigation, became firmly convinced that no permanent good could be accomplished except through the persistent efforts of an organized society, the object of which would be not only to educate all lay people but to keep the needed facts constantly before the family practitioner, for it is to him that the patient will apply for what may appear as a slight and insignificant matter.

In the course of their investigations these conclusions were laid before several philanthropic men and women. Through their efforts and the hearty cooperation of prominent surgeons, the committee was instructed to report to the American Gynecological Society that a permanent organization would be formed provided the various national surgical and medical organizations should consider that such a society was needed. The formation of such a society was unanimously endorsed by all the interested national associations composing the Congress of Physicians and Surgeons of America. The movement was later unanimously endorsed by the American Medical Association.

The society has been fully organized. It is known as the American Society for the Control of Cancer, and has upon its board of trustees prominent lay people, both men and women, together with physicians and surgeons throughout America. Its membership list will be open to all who may wish to help in educating men and women for their own protection.

The objects of this society are many. Lay people will be informed through the daily press and through periodicals and by lectures of the necessity and of the importance of consulting their physicians on all matters in which there are departures from what is normal. The busy general practitioner, meting out help as he does from his rising until late at night, will have it frequently impressed upon him that all cancers have a small beginning and as such their significance may be overlooked, unless studied and definitely proved not to be of such a nature. What wonder it is that this busy and big hearted man should wish to encourage and reassure his patients, and the temptation is great to do this by a quick and superficial examination. Such a desire is inborn in the man of many patients and of a big heart. It will at times be difficult for him to insist on a thorough examination and determination of the true character of what appears to the patients as some trivial matter for which they desire only an ointment or a wash. The knowledge, however, that by following such a course lives can be saved which would otherwise be sacrificed, will a thousandfold repay him for his painstaking care and conscientious study.

The scientific side of the problem will also be fully undertaken as to the value of the old and the recurring new methods of treatment. In this age of civic and benevolent orders, when we know that for all ages 130 women out of every 100,000 die of cancer of the uterus and the breast, and that between the ages of forty-five and sixty-four, one out of every eleven deaths in women is due to cancer of these organs, of which two thirds are from cancer of the uterus, we are forced to wonder that a national movement has not been started in America before.

A lump in the breast is at once detected, the patient has been educated to know its significance. She seeks advice at an early date and under the modern methods of treatment has every opportunity of being cured. This cannot, however, be said of cancer of the uterus. Here nothing is visible to the patient and the disease involving this organ does not have pain as its danger flag. This is absent in the earlier stages of uterine cancer, the curable stage, and it is only present in its later stages when the disease has extended into the surrounding tissues and is pressing upon the nerve ends. The monthly recurrence of the menstrual flow necessitates a certain amount of information that is sought by and imparted to the young woman. With increasing age this is added to by her female relatives and friends. Such knowledge passed from one to another has given rise to many erroneous ideas which have taken firm root in the minds of women. Chief among these are that the change of life commences around the age of forty-two, instead of the average of forty-seven, as has frequently been determined. Associated with the advent of this period it is the common opinion that the monthly flow is expected at times to be very profuse and at others even to extend over a considerable period with evidence of only slight coloration. There can be nothing more dangerous to the welfare of woman than such hereditary ideas. Through such ideas many women have been lulled into a feeling of security until forced to consult a physician, only to find that time that was invaluable has been lost and that the condition, if cancer, it proves to be, has passed beyond the curative stage.

Cancer of the uterus occurs either in the body of the uterus or at its more exposed lower portion, known as the cervix. The great majority have an origin in this last mentioned part. The commonly attributed cause for this more common location of the disease is the constant local irritation due to extensive unrepai red tears that have resulted from childbirth. A counterpart of such a sequel is seen in the occurrence of cancer of the cheek in women of Central India, where the habit of chewing and carrying the betel nut within the cheek is common. There is also the smoker's cancer of the lip from the pipe. Another instance is that of the occurrence of cancer of the abdominal wall in cer-
tain tribes of Thibet who are in the habit of wearing a warming pan against the abdomen; also the chimney sweeps' cancer of the groin from irritation of the acid soot. Cancer of the stomach is recognized as having its origin at times in the scars of ulcers, and Mayo states that it is a question whether the supposed repeated medical healing of ulcers of the stomach relieves the tendency to cancer.

It will be seen that the accepted opinion of surgeons that the constant local irritation of severe lacerations of the uterus predisposes the woman to cancer is abundantly sustained by like occurrences in other localities. For this reason it is highly important that such lacerations and erosions due to irritating discharges should be repaired in the former instance and excised in the latter; primarily as a curative means of conditions that give rise to a well marked nervous train of symptoms, and secondarily as a means of prophylaxis against the possible sequel of cancer. It is not considered the best practice to repair such lacerations immediately after the birth of the child, on account of the possibility of infection. A thorough examination should be made some months after the labor and when cervical lesions of any magnitude exist the patient should be informed of it and repair instituted as early as possible.

Cancer of the cervix takes on two characters. The one in which a spongy mass develops, readily bleeding on touch; this is called the everting type; the other commences more within the canal of the uterus at its opening. This is known as the inverting type. The latter type is more prone to recur than the former after a removal.

The occurrences that should attract the attention of the patient and cause her to consult her physician are the appearance of a persistent leucorrhoeal discharge which did not previously exist. This discharge is later tinged at times with blood, especially on exertion. At other times the leucorrhoea may not be so prominent, but the first evidence may be a slight recurring show of blood or a bloody discharge between periods, which is accentuated by the touch of a douche pipe or otherwise. The flow may amount to a sudden profuse hemorrhage, but more often the amount is scanty, ceasing after a short time to recur at intervals on exercise, or on bending over. When such conditions occur at or near the age of the change of life, it is too often mistaken for some of the attendant vagaries of this period, a previous distorted knowledge having been absorbed by the younger generation of women from those who have gone before. Being armed with such erroneous ideas she fails to seek advice until the disease has advanced beyond the earlier stages. During the earlier stage, as has been stated, pain is as a rule absent. This is another erroneous conception frequently held by women, that nothing can be radically wrong in the pelvis if they do not have a feeling of discomfort and pain in this region.

With the absence of pain and discomfort they attach no importance to irregular show of blood especially if this should occur at or about the period of their lives when all women expect irregularities. Cancer of the body of the uterus from the stand-point of the patient has all the early symptoms of cancer of the lower portion (the cervix) of the uterus. They are irregular bleeding, watery discharge at times dark colored and the same absence of pain, as in the former instance. These symptoms having been given us by the patient on her first consultation it is our imperative duty to the patient to insist on a thorough local examination. The results of such an examination will give a full view of the neck of the uterus and will enable the physician to state whether cancer is present or whether it is absent. There are times when the involved area is doubtful. This is especially true in the earliest commencement of cancer of the cervix. Under such circumstances there is only one course to follow, that of speaking frankly to the patient or her relatives and urging that the diseased part shall be removed and submitted to a competent microscopist for examination. In general I think it best that when such an examination is needed, the patient should be placed in a hospital, and under general anesthesia, the part in question is removed and at once frozen and examined under the microscope. This method of procedure has many advantages over removing for examination such a section under cocaine in the office. Chief among these are that such an office procedure opens up lymph channels of absorption carrying further up into the uterus the cancerous juices if such a condition should be present. If the examination proves that cancer is not present, the patient being still under anesthesia can be given the benefit of having the neck of the womb repaired which she was evidently in need of and thus removing what was an irritating condition, and the possible cause of a future cervical cancer. If the examination shows that no disease of the neck of the womb exists, the examination must be extended to the inside of the body of the uterus to prove or disprove the presence of cancer of this part. This examination should not be done in the office. It should be done under an anesthetic with all surgical care. Under the anesthetic the uterus may be found to be a little larger than normal. The scrapings from the inside of the uterus are saved and submitted to the pathologist for a diagnosis. Many times the diagnosis of cancer is at once evident from the abundant brainlike material drawn away; at other times the decision of the pathologist must be awaited.

There are three conditions other than that of cancer that bring about irregular uterine bleeding. The one, harmless cervical polyps and also fibroid tumors of the uterus. The polyps are easily removed and the bleeding stopped. If there is any question of the presence of a fibroid or that cancer is the cause of the bleeding, an examination of the scrapings by the pathologist will determine the matter. The other two are miscarriages and extrauterine gestation. This history in both of these instances will lead us to suspect the condition; and in extrauterine gestation the pelvic condition outside of the uterus will usually prove the true state of affairs.

If the general practitioner will bear these elementary facts constantly in mind and with a fixed conscientious purpose, give every patient with questionable symptoms the benefit of a thorough local
examination the story that is now being told will soon be changed in many respects. **Bear always in mind that cancer in its earlier stages is a local disease and as such can be cured.** Many women leading useful and valuable lives to-day can attest to this statement. The experience in all clinics in America is that it is rare that more than one out of every four who apply with cancer of the uterus can be given any treatment other than something to ease their pain and make their short period of life more bearable. In a collection of all cases of cancer of the uterus who have entered the Woman’s Hospital during the last six years; i.e., patients who have been sent there in hopes that something can be done, there were eighty-six patients with cancer of the cervix and vagina and 125 with cancer of the body of the uterus. Of the eighty-six cases of cancer of the cervix twenty-one, or less than one fourth, were discharged as possibly cured, that is such an operation was done as to insure every possibility of there being no return of the disease. The remainder could be given only palliative treatment.

Of the 125 cases of cancer of the body of the uterus, forty-one, or about one third, were discharged as cured. Among the remainder the disease had existed for such a length of time as to have extended beyond the uterus and had involved other organs.

This is a discouraging report and especially so when we recognize that in cancer of the body of the uterus the disease is of such slow progress that even though it may have existed for some time it is still confined to the uterus and we expect to cure almost every patient.

This same discouraging lack of intelligent self care existed in Germany and elsewhere abroad prior to ten years ago. Winter keenly appreciating this fact undertook a personal campaign of education on the subject of cancer in 1902 after moving to Königsberg, Prussia. His efforts were directed to educating physicians, midwives, and lay people. The results of his spendid labours have been far reaching, exciting similar movements in almost every country. The immediate results of his work in and around Königsberg he gives in a chart which is of much interest. Before commencing his propaganda the records of his hospital showed that for the three years prior to 1902 only thirty per cent. of the patients applied for relief within three months after the first symptoms. In 1903, the year following his educational efforts, fifty-seven per cent. applied within the above time. Among patients applying to midwives forty-six per cent. were prior to 1902 referred to hospitals as soon as the symptoms were known, while in 1903, the year following Winter’s movement, eighty-six per cent. were referred.

Such a system of education can only be productive of the greatest good and has been felt throughout all of the Continental hospitals where, in nine of the largest, sixty per cent. of the patients applying for relief have come sufficiently early to be given the opportunity of a permanent cure: while in our own country, with the exception of one hospital, twenty-five per cent. will be a liberal estimate for those capable of being benefited by a complete operation for cancer. Wertheim, whose name is prominently associated with the complete operation for cancer, reports 1,430 cases seen in his clinic in fourteen years. Of this number fifty per cent. were operable, that is, half of them were patients who had a fair chance of being cured and included not only those in the very early stages where cure was almost a certainty, but those more advanced and still those in whom there was a question of the benefit of any operation. Including all of these three grades of advancement of the cancer, forty-three were cured.

Faure, in a recent review of 250 cases of cancer of the cervix operated on in since 1896, divides the patients into three classes: 1. Those of early cancer in which the disease invaded only one lip of the cervix. In such the mortality was five per cent. and the subsequent return of the disease was the rare exception. 2. Those in which both lips of the cervix were involved, together with the vaginal mucosa and the base of the broad ligaments. Among these the operative mortality was twenty per cent. and the return fifty per cent. 3. Those in which the mobility of the uterus was almost lost. Here the mortality was fifty per cent. and the recurrence the rule.

These statistical data which may be of very little interest to you bring out strongly the one fact I am anxious to impress upon you, that cancer is curable and that the time when this is possible is in the earlier stages of the disease. It is at this time that the patient will appeal to you, the general practitioner. The responsibility is therefore yours, that correct and early diagnosis is made within the time when something of value can be done. It is for you to sight the danger flag when slight and apparently insignificant symptoms are mentioned by your patients. I beg of you not to treat such statements lightly but follow them up with close questioning and insist on an examination which should be thoroughly made. It is only in this way that you can fulfil the obligations placed upon you.

It matters little what may be the treatment of the future, whether by surgery, radiotherapy, chemical remedies, or immune serum, we must still have early diagnosis and early treatment as the basis on which our hopes are centred.

**148 West Seventy-seventh Street.**

**DIAGNOSIS OF ACUTE ABDOMINAL CONDITIONS.***

By J. Thompson Schell, M.D.,
Philadelphia.
Chief Surgeon to the Northwestern Hospital.

The diagnosis of the various intraabdominal conditions is always attended with great difficulty, and at times creates a great uncertainty in the mind of the attending physician or surgeon. The fact that various pathological conditions can produce almost identical symptoms makes the solution of the puzzle difficult, calls for the highest type of analysis, and entails painstaking care and careful thought. In spite of all care and close, minute, and repeated

*Read before the Northwestern General Hospital Medical Society.*
examinations, mistakes are frequent. It has been
my experience to be compelled to change my diag-
nosis many times after opening the abdomen, and
I have witnessed the same experience in the hands
of the ablest and most skilled men in the profession.
This state of affairs should not discourage us, but
only urge us on to renew our efforts, as human life
is oftentimes dependent upon our diagnostic skill,
and sacrificed by the lack of the same. It is a com-
mon experience to see gallbladder disease, gastric ulcer,
appendicitis, ovarian inflammation, etc., mistaken
for one another, and many times even after the
abdomen is opened, the riddle remains unsolved.
Notwithstanding all this, much progress has been
made in the last decade, and much of this progress
can be traced to the opportunities offered to the
abdominal surgeon to study, as Deaver puts it, the
“living pathology,” at close range.

In a brief article of this kind, no attempt will be
made to delve into the finer points of the symptom-
atology of the various abdominal diseases, but I will
call your attention to some of the more reliable
symptoms and their possible meaning in order to
refresh your memories, and possibly bring out a
discussion that oftentimes is of more value than
the original paper. The subject is such a large one that
I will begin by dividing it into the acute and chronic
diseases, and will take up only an analysis of the
acute diseases, or those presenting acute symptoms.

In the acute abdominal diseases not only are we
called upon to make an accurate diagnosis, but
the question of operation must be settled, and settled
quickly. When called to the bedside of a patient
suffering from acute abdominal condition, every ef-
fort, therefore, should be made to make a diagnosis
at as early a period as possible. This diagnosis
should include not only the viscus involved, but also
the character of the pathological process whenever
this is possible. For practical purposes to aid in
analysis of the symptoms it may be of some aid to
divide the symptoms into the following groups:

1. Inflammatory symptoms—Those whose most
characteristic symptoms are the result of inflamma-
tion.

2. Pain—Those where pain is the leading or most
suggestion symptom.

3. Intestinal obstruction.

4. Shock due to internal hemorrhage.

While these divisions have been of considerable
help to me in the past, and may be of some use to
you, it must not be forgotten that a condition which
ought to be found theoretically under one heading,
will occasionally be found under another. On the
other hand, if we train ourselves to a systematic
method of thought, the presence, for instance, of
pain, will suggest at once to us the condition tabu-
lated under that heading, and we shall be less likely
to make an error. More errors of diagnoses, in
my opinion, are due to careless methods than to lack
of knowledge; more often the error is a sin of omis-
sion, rather than of commission.

GROUP I. INFLAMMATORY SYMPTOMS.

The group symptoms of early suppuration are
fever, sometimes chills, leucocytosis, and increased
pulse rate. Under this heading are placed the fol-
lowing:

A. Acute cholecystitis.
B. Hepatic infections—Single tropical abscess.
Suppurative pylephlebitis. Catarrh and suppurative
cholangitis. Suppurative echinococcus. Multiple
abscess of liver.
C. Primary peritonitis—Acute tuberculous. Pneu-
monicoccus. Gonorrhœal.
D. Renal infections—Pyleonephrosis. Pyleo-
phritis. Metastatic abscesses.
E. Subphrenic abscess, usually secondary.
F. Perforations of (gastric, duodenal, typhoid) ulcers; shock following immediately.
G. Acute pancreatitis; agonizing pain and col-
lapse.
H. Renal colic; pain referred to testicle and along the ureters. Uranalysis will probably help.
I. Torsion of ovarian pedicle; locality, history, and pelvic examination. Shock and rapid pulse
suggest beginning of peritonitis.
J. Visceral crisis (tabes); never to be forgotten.
K. Referrred pain from thoracic and abdominal
diseases.

GROUP II. PAIN.

In this group are placed the diseases in which
pain is often the first or most characteristic symp-
tom, and thus suggestive in a practical clinical way.
They are as follows:

1. Appendicitis; locality of the pain.
2. Gallstone; pain coming on when relaxed, and
also locality.
3. Perforations of (gastric, duodenal, typhoid) ulcers; shock following immediately.
4. Acute pancreatitis; agonizing pain and col-
lapse.
5. Renal colic; pain referred to testicle and along the ureters. Uranalysis will probably help.
6. Torsion of ovarian pedicle; locality, history, and pelvic examination. Shock and rapid pulse
suggest beginning of peritonitis.
7. Visceral crisis (tabes); never to be forgotten.
8. Referrred pain from thoracic and abdominal
diseases.

GROUP III. ACUTE INTESTINAL OBSTRUCTION.

The patient, as a rule, has, 1. sudden abdominal
pain; 2. constantly recurring vomiting; 3. ob-
structive constipation; and every effort to secure a
passage of feces or flatus results negatively.

Constipation is often the first symptom; then
vomiting, which is first, of indigested food; second,
of mucus; third, of bile; fourth, of feces, the last
usually not until the third or fourth day, and diag-
nosis should be made before this symptom develops.

Pain as a symptom of this condition is not relia-
ble, as it is marked only when caused by volvulus,
tintussuction, bands and hernial kinking.

Increasing tympanites is a valuable and dangerous
symptom; the pulse rate is not rapid until the onset
of peritonitis, which later appears as a complication.

In this group are: 1. Strangulation by band, ad-
hesions, hernial opening. Meckel’s diverticulum.
2. Volvulus. 3. Intussusception. 4. Tumors.
5. Adynamic obstruction.

GROUP IV. SHOCK DUE TO INTERNAL HEMORRHAGE.

Symptoms of internal hemorrhage as follows:
Face and mucus membrane pale and blanched,
great restlessness, thirst, repeated attacks of syn-
cope, rapid weak pulse, abdomen rigid (tender, but
not so marked as in peritonitis), temperature at first
subnormal, cold extremity and sweats, later some elevation.
In this group are: 1. Extrauterine gestation. 
2. Rupture of aneurysm. 3. Perforations of hollow viscer are included also in this group, as well as in group II. It can be readily seen now that this classification is far from complete, and that a number of conditions can be correctly placed in several groups; but I have attempted to classify according to the most prominent symptoms present in each condition.
A few words now as to differential diagnoses of the diseases most likely to be mistaken one for the other.

ACUTE APPENDICITIS.
1. Muscular rigidity marked.
2. Pain begins higher and soon located at McBurney's point.
3. Tenderness right iliac fossa.
4. Nausea appears in a few hours.
5. Bimanual examination negative.
6. No history; indigestion, gonorrea or other infections.

Two conditions, however, may complete one another.

GALLSTONES.
1. Early fever due to cholecystitis, however.
2. Vomiting is an early symptom and more persistent.
3. Pain is more severe and colicky in nature.
4. Tenderness and rigidity higher up.
5. History of primary infection.

The study of the symptomatology and diagnosis of gastrosis, chronic dilatation, pyloric obstruction, gastric volvulus, and hourglass stomach, would require a separate and distinct thesis, but the limits of the paper will only permit touching on the most prominent and practically diagnostic symptoms of the more common diseases within the abdomen.

Acute gastric dilatation on the other hand, is a subject of great importance to the surgeon, and is frequently the cause of postoperative deaths that are mistaken for postoperative shock. Hilton Fange, in Guy's Hospital Reports, 1872 and 1873, first described this condition and since then Albrecht, in 1809, reports nineteen cases; Thomas, in 1902, forty-four cases. Since then many more cases have been reported, but notwithstanding this the condition is very often overlooked. The onset is sudden, twelve to twenty-four hours after the operation: epigastric pain; feeling of distention; vomiting without effort of large quantity of greenish gray fluid with no relief; vomitus not offensive; great distention of upper abdomen, especially on left side: splashing; introduction of tube gives relief only for a time. No operative treatment is of avail. Lavage will cure the early cases; it is only the cases that are overlooked that are beyond aid.

Gastric ulcer: Striking feature "remission." Most classical symptoms pain, vomiting and hema
tesis.

Pain: Ulcer on posterior wall and lesser curvature is to left of median line; nearer the cardiac end of stomach; the pain is higher in the epigastrium.

In pyloric ulcer, the pain is later and more to the right. Lesser curvature pain is later and relieved by taking food. If the ulcer is on the anterior wall the pain is often referred to the left shoulder. Tenderness may be deep or superficial. Superficial tenderness is of no value as it is too misleading. Deep tenderness and rigidity is very suggestive. If high to the upper left of the rectus, the ulcer is at cardiac end; if to the right, it is usually pyloric; in the neighborhood of the ninth to the tenth dorsal spine tenderness is always to be looked for.

DIFFERENTIAL DIAGNOSIS OF GASTRIC ULCER.

Gallstones: Textbook symptoms are late symp
toms.

Inaugural symptom: Pain within an hour of taking food relieved by belching, chilliness after eating; pain not so regular; vomiting associated with more retching and no relief of the pain unless the stone passes.

Tabes: Diagnosis of same.

Appendix: Pain is epigastric; attacks often due to exercise, vomiting rare, nausea frequent, much chronic dyspepsia between attacks; symptoms of gastric ulcer, supposed to be due to pyloric spasm.

A few words in reference to two not so well known abdominal conditions:

Meckel's diverticulum, congenital abnormality of the small intestine due to persistence of the intra-abdominal part of the vitelline duct, which is obliterated during the sixth or seventh week of fetal life; usually at the convex border of ileum within two feet of its termination at the ileocecal valve. It is present in two per cent. of all human beings, and in form may be of one of the following varieties: 1. Small thimble shaped pouch. 2. Umbilical fistula. 3. Sinus—with blind end in the abdomen. 4. Tubular form has its own mes<ref>ency. 5. Sometimes forms a cystic tumor. The diagnosis depends on the complications, such as inflammation, intussusception, volvulus and strangulation, the last being the most frequent.

Hirschsprung's disease—idiopathic dilatation of the colon—is found in young children, especially boys; the symptoms are chronic constipation, extreme abdominal distention, colon dilated and hypotrophied, muscular coat thickened; small intestine normal. It usually affects the pelvic colon only. The treatment is usually medical. The surgical treatment is by resection, Anastomosis, and sometimes, colostomy. Coloplexy and coloplication are not successful.

At times, however, the differential diagnosis between these conditions is impossible, and can be made only by an exploratory incision, and the operation must be planned accordingly.

In conclusion, I should like to impress upon your minds, as I said in the beginning, that it is only by careful examinations and analyses that we can hope to have the least number of mistakes, and for illus-
tration take the old term indigestion. Indigestion is always a symptom, and never a disease. The sooner we get this fact clearly and conclusively settled in our minds, the better it will be for our patients. The patient who seeks relief from the various symptoms of indigestion cares little for the scientific classification of his or her illness, but wishes prompt and speedy results, and the doctor in his anxiety to bring about brilliant symptomatic cures very frequently does not seek for the actual underlying disease.

That we only have ourselves to blame for the many so called schools of medicine, which are now cropping up everywhere, I sincerely believe, for if we were more painstaking and careful in making diagnoses, and were never satisfied with the treatment of symptoms, there would be so few dissatisfied patients that the irregular practitioners would receive such poor support that their existence would be temporary indeed. Mayo, in 1900, strongly advised the medical profession, where any cases of cancer of stomach were suspected, to call in a surgeon, and insist on an early exploratory incision. His advice, also that of many other surgeons, has gradually become more and more accepted, and exploratory operations are more often resorted to each year, with some very gratifying and brilliant results.

While I believe that the radiologist, the laboratory worker, the clinician, and the surgeon should work hand in hand, my experience has been that a great deal of valuable time is often times lost by undue examinations, and at times have found that both the x ray and laboratory findings are confusing, and rather tend to, than prevent, diagnostic errors. To my mind, a careful history, combined with a painstaking physical examination and a moderate amount of medical treatment, will in the majority of cases serve the best interest of the patient, and will give sufficient data to decide as to the justification of an exploratory incision. I have at this time a patient who has been subjected to four analyses of stomach contents and one x ray picture, and the diagnosis was not made until an exploratory operation revealed a scirrhous carcinoma at the pylorus, on which a partial gastrectomy was done; also another patient who gave a history of seven years of chronic indigestion with acute exacerbations of pain and vomiting, and who in the last attack finally fell unconscious on the street. A hurried operation showed a gangrenous and adherent appendix, no doubt the actual cause of his long drawn out obscure illness.

In addition to this, within the last year, I have removed a surgical kidney containing a large stone and multiple foci of purulent infection. The patient had been treated more or less constantly for chronic intestinal indigestion. I have just discharged another patient who, after repeated examinations, both in this country and abroad, including all the accepted methods, and on whom three different diagnoses were made, has been cured by the removal of a large and edematous subperitoneal fibroid, which had reflexly produced her symptoms. These suggestive and illuminating experiences are the common experiences of every medical man, and surely argue very forcibly in favor of an early and correct diagnosis, and I know of no other as definite and precise method as the actual surgical incision. I do not wish to be understood as advocating an exploratory operation in all cases of indigestion, but I do think that patients who give histories of long drawn out indigestion, should be held guilty of harboring in their abdominal cavities some serious pathological condition, until it is proved otherwise, either by an absolute disappearance of the symptoms by careful (but not too long drawn out) medical and dietetic treatment, or by an exploratory operation.

I have about reached the conclusion that chronic and relapsing indigestion is just another way of saying that the patient is suffering from a real pathological change in one of the many intraabdominal organs, and we should never rest satisfied until the offending kidney, gallbladder, stomach, duodenum, uterus, appendix, pancreas, or what not, is ferreted out, and properly treated, and I know no other methods that are as sure, safe and reliable as first, a careful history; second, a precise and painstaking physical examination; and last, but not least, an exploratory incision.

1832 Diamond Street.

THE INDICATIONS FOR OPERATING IN ACUTE MASTOIDITIS.*

By Gerhard Hutchison Cocks, M.D.,
New York,
Assistant Surgeon, Manhattan Eye, Ear, and Throat Hospital, Ear and Throat Departments.

In many cases of acute mastoiditis the indications for operation are perfectly clear. In a large number of instances, however, the surgeon is confronted with considerable difficulty in deciding just when to operate. He desires, on the one hand, to avoid surgical interference if the patient will recover without it; on the other hand, he is even more anxious to avoid labyrinthine or intracranial complications by not unduly delaying operation.

One of the most constant symptoms of acute mastoiditis is pain over the mastoid. This pain is almost invariably worse at night, and is often described as “boring” in character. The patient may volunteer the statement that during the early stages of the otitis the pain was felt in the ear itself, but now is experienced over a different area, the mastoid region. In some cases, however, the pain is not felt over the mastoid bone, but over the parietal bone and the side of the head above the auricle.

Insomnia naturally accompanies pain in mastoid disease. We must remember that mastoid pain is not always present. A few months ago a woman was referred to me because of sudden unilateral deafness. On examination, I found acute purulent otitis media, with a slight amount of discharge in the canal. The patient complained of some discomfort in the ear, but no pain. I treated her for two and a half weeks, performed myringotomy three times, and finally opened the mastoid, which was filled with pus. From first to last she refused to

*Paper read at the annual meeting of the American Academy of Ophthalmology and Otolaryngology in Chattanooga, Tenn., October 27, 1913.
admit that she suffered from pain. The indications for operating in this particular case were: 1. A bulging drum, in spite of repeated myringotomy. 2. No cessation of the discharge after two and a half weeks. 3. Moderate, persistent antral and tip tenderness. 4. Slight sagging of the superior canal wall. In this patient, a culture taken from the mastoid pus at the time of operation showed a growth of pure Streptococcus mucosus.

Elevation of temperature is a much more frequent symptom of mastoiditis in infancy and childhood than in adult life. Systemic disturbance is often shown by marked prostration, and by a heavily coated, tremulous tongue. The furred tremulous tongue should always be looked for, and should be given due weight in judging the patient’s condition.

Tenderness upon pressure is one of the cardinal signs of mastoid suppuration; and is probably the most constant. It is well to remember that during the first twenty-four to thirty-six hours of an attack of acute purulent otitis media, there may often be slight tenderness over the antrum or tip of the mastoid. This tenderness disappears after myringotomy,—in uncomplicated cases,—only to return a few days later when the mastoid process becomes involved. In the more severe cases of mastoiditis, pressure tenderness may be present from the start. There are four points where tenderness may be elicited: 1. Over the mastoid antrum, i. e., just behind the superior attachment of the auricle. 2. At the mastoid tip. 3. Over the posterior part of the mastoid, at the point of emergence of the emissary vein. 4. Over the posterior root of the zygoma, where the so called zygomatic cells are located.

Sagging of the posterosuperior canal wall is another of the cardinal symptoms of mastoiditis. As a rule, it is not present early in the disease and it is usually accompanied by bulging of the drum membrane. In this connection, it is well to remember that we occasionally encounter mastoiditis with an almost normal drum membrane. However, the otoscopic picture will usually show a drum membrane red, angry, and bulging, which does not in any way suggest that the middle ear lesion is subsiding.

Anterior displacement of the auricle and edema over the mastoid are present in advanced cases of mastoiditis where perforation of the mastoid cortex has occurred. Furuncle of the canal is, however, a far more frequent cause of retroauricular edema.

In some cases we find a diffuse swelling beneath the sternomastoid muscle, due to pus perforating through the mastoid tip into the digastic fossa,—the so called Bezold type of mastoiditis.

In an ordinary case of acute otitis, the discharge is at first serious; later, purulent; and, finally, as the inflammatory process subsides, the discharge diminishes in amount and becomes mucoid.

In mastoiditis, instead of the patient’s condition improving as the discharge ceases, we find that the cessation of the discharge is accompanied by an increase in the amount of pain, mastoid tenderness, and constitutional symptoms due to obstructed drainage. Or, again, the amount of discharge may be so great that we know it is a physical impossibility for it to come from the tympanum alone. The mastoid cells must necessarily be involved. Thus we see, in mastoiditis, that the character and amount of the discharge are of value in helping us to arrive at a diagnosis.

The bacteriology of the aural discharge is often of considerable diagnostic value. A smear and culture should be made at the time the myringotomy is performed. Wittmann studied fifty-five cases of acute purulent otitis media. He found ordinary streptococci twenty-four times; Streptococcus mucosus, twenty-one times; pneumococci, ten times; in seventy-five per cent. of the mucosus cases mastoiditis developed.

Libmann examined a series of 141 cases. He found streptococcus in eighty-eight cases (pure in seventy-nine); pneumococcus, eight times; Streptococcus mucosus, ten times; Staphylococcus aureus, four times; Staphylococcus albus, three times; Bacillus proteus, once; Bacillus pyocyaneus, twice.

It is now quite generally recognized that Streptococcus and Staphylococcus mucosus are more apt to cause acute mastoiditis than the pneumococcus or staphylococcus. In cases where the indications for operation are not perfectly clear, given the Streptococcus mucosus, we would feel it our duty to operate at an earlier period than otherwise. Occasionally meningococci are found in the discharge from the ear. This means that the patient is suffering from meningitis, or that meningitis is likely to develop.

One should remember that the pus from the canal is apt to present a mixed infection, with certain germs predominating, while the pus from the mastoid is much more apt to show a pure culture.

The blood count cannot be relied upon to differentiate acute otitis from acute mastoiditis. It is, however, of considerable value in determining the presence of such complications as meningitis, brain abscess, sinus thrombosis, or glandular involvement. McKernon, in the Buffalo Medical Journal, April, 1913, gives his conclusions, based on the study of the blood examinations in 400 aural cases. He states his belief that these examinations will show two things:

First: The resisting power of the patient, as shown by the number of leucocytes present, which, if over 15,000, shows a good resistance. If daily examinations show a steadily increasing number of white cells, we infer that the patient’s resistance is improving, even though the inflammatory process is more pronounced. If, on the other hand, there is a small number of leucocytes from the first, the patient’s resistance to the disease is poor, and during the further progress of the disease, should they steadily decrease, the resistance becomes still poorer, and frequently this an indication for an urgent operation, or calls for one being done earlier than would otherwise be necessary.

The second point of value for the clinician is the polynuclear percentage, which shows definitely the amount of absorption taking place in the system as a result of the existing suppurative process. The normal percentage in the adult varies from fifty-five to seventy in the child, from forty-two to sixty. In a supplicative lesion of the mastoid process without complications, the polynuclear percentage ranges from seventy to eighty; where adjacent structures are involved, as the blood current in the sinus or vein, it ranges from eighty to ninety-six. In other words, the higher the polynuclear percentage the greater the absorption and the more urgent the demand for operative procedure, and this is especially true if frequent examinations show a steadily decreasing
number of leucocytes. If, however, repeated examination show a decreasing polymuclear percentage with a stationary or slowly decreasing leucocyte count, it is evident that the suppurative process is diminishing and that Nature is eliminating the poison from the system.

The relation between the leucocytosis and the polymuclear is the valuable feature. Increasing leucocytosis, with stationary or falling polymuclear, indicates better resistance and less absorption; while decreasing leucocytosis and increasing polymucicular indicates less resistance and a greater absorption.

The preservation of the hearing must always be considered in deciding for or against operation. In certain border line cases, where the indications for the mastoid operation are not entirely clear, a marked diminution in the patient’s hearing, especially in the presence of other symptoms, would induce us to operate at once. On the other hand, we know perfectly well that this type of case very likely may end in recovery without operation, but with the sacrifice of considerable hearing. To sum up: Marked diminution of the hearing, in certain border line cases, is an additional indication for opening the mastoid.

Radiography of the mastoid is a valuable aid in deciding when to operate. It also furnishes information in regard to the anatomy and pathology of the mastoid bone. Doctor Law, radiographer of the Manhattan Eye, Ear, and Throat Hospital, has written an excellent paper on this subject, from which I shall quote freely: “The x ray plate shows: 1. The size and extent of the mastoid cells. 2. The position of the lateral sinus and emissary vein. 3. The presence of pus or granulations in the mastoid. 4. In chronic cases, cholesteatoma. 5. Sometimes, the presence of sclerosis. In the x ray plate the normal mastoid shows as a dark area, while the bony partitions between the cells appear as light lines. In the bony structures of the skull the sinus and emissary vein are seen as dark streaks. Where the lateral sinus crosses the mastoid, the cavity of the sinus is superimposed upon the cavities of the cells, and consequently the outline of the sinus is less distinct. In cases where the lateral sinus stands out very clearly in the mastoid bone, we are dealing with either pathological material,—i.e., pus or granulations in the cells—or with a dense hard cortex. In the normal plate, the auditory canal appears as a dark spot, about one quarter of an inch in front of which is seen the articulation of the jaw. When the outline of the auditory canal is rendered indistinct by the presence of pus, the location of the shadow cast by the pinna and the condyle of the jaw aid in determining its site.”

Mastoiditis, according to Law, “is shown by the appearance of the cells as compared with the normal side. This may vary from a slight hazy appearance to complete occlusion of the cells. In a mild condition, there is a slight haze over the cells, but the bony partitions are still intact. As the condition progresses, the haziness increases; light spots appear, which indicate collections of pus or spots of granulations. In a severe case, the haziness becomes a dense white blur, with no partitions visible, the lateral sinus standing out clear, and the auditory canal barely showing.”

Occasionally a case of furuncle of the external auditory canal is encountered, accompanied by intense edema of the canal, auricle, skin over the mastoid, and side of the head. Further to complicate matters, we may get a history of a purulent discharge from the canal. We elicit a certain amount of soreness or pain upon pressing over the mastoid, and are uncertain in our own mind whether it comes from mastoid disease or from the furuncle. In such cases as this, the x ray examination is our sheet anchor and can be depended upon to clear up our dilemma.

THE RELATION OF HYPERTHYROIDISM TO THE NERVOUS SYSTEM.

With Report of a Psychosis Occurring Four Years after Thyroidectomy.*

By Albert C. Buckley, M.D.,
Philadelphia.

To one examining the literature of the last twenty years upon the subject of disease associated with hyperplasia of the thyroid gland, it would seem at first sight that the nervous system is credited with almost all the responsibility, causally considered, in the production of the conspicuous and almost constant symptoms. The alleged factors in the cause of exophthalmic goitre and its accompanying syndrome cover a field extending from eyestrain to hemorrhage and degeneration in the central nervous system. Certainly there is much to attract the attention to the nervous mechanism. Just how much that is concerned is yet to be told. It is very clear that the nervous system is implicated to a serious extent. There is much evidence to show that the disease occurs in individuals who seem to be predisposed in that they are the possessors of inherently unstable nervous systems. Exophthalmic goitre and nervous diseases including insanity occur frequently in different members of the same family. An exophthalmic woman is recorded as having a daughter a cretinoid idiot. F. H. Packard analyzed a series of eighty-two cases of Graves’s disease with mental disorder, with physical signs “tolerably well marked”; twenty of the patients were men and sixty-two were women. He found a neuropathic heredity marked in sixty-three per cent. In six per cent. there was a definite heredity for Graves’s disease. Of the whole number, fifteen per cent. had suffered attacks of mental disorder before the thyroid disease was noticed, so that the psychoses might have developed without the goitre.

The symptoms of hyperthyroidism as seen in exophthalmic goitre present the antithesis of the syndrome associated with absence of the thyroid. They correspond rather with the symptoms attending the administration of thyroid gland in full doses. Comparing the two conditions, it is well known that in myxedema there is slowness of the pulse, cold, thick, and dry skin, and sluggishness

*Read at a meeting of the Philadelphia Clinical Association, November 3, 1913.

†American Journal of Insanity, October, 1909.
and dullness of the mental powers, in some instances amounting to idiocy or imbecility. In hyperthyroidism there is rapid action of the heart, the skin is thin and apt to be moist, and there are signs of increased nervous activity in the form of tremors, excitability, and mental irritability. According to Magnus Levy, the respiratory exchange of gases is increased by fifty per cent. Sugar tolerance is diminished so that glycosuria may occur. Sufferers from chilblains and ordinary colds are said to become immune when they become hyperthyroid, and tuberculosis, it is stated, rarely occurs in uncomplicated cases of Graves's disease.

By far the majority of patients suffering from hyperthyroidism present mental symptoms in some degree. In fact, mental symptoms may be the earliest noted, that is before the cardiac or ocular symptoms become manifest. The most commonly noted are an intense and indefinite agitation with more or less mental and motor restlessness. The patient is unable to settle down to occupation and complaints of being distressed by any sudden noise, or unexpected news, this being accompanied by a palpitation that may last for several hours. Other patients suffer with marked excitement, restlessness, sleeplessness, hallucinations, incoherence, violence, refusal of food, dirty habits, emaciation, diarrhea, and exhaustion which may terminate fatally.

In 1883, Savage, in Guy's Hospital Reports, reported several cases of insanity with Graves's disease, with the conclusion that when insanity is associated with exophthalmic goitre the prognosis as to life is very great. Three of his cases were of a severe type; two cases terminated fatally. With marked and distressing palpitation the patients later became dull and sleepy and died of exhaustion. Another case began with mental depression followed by a maniacal state. Some instances of recurrent insanity are mentioned in which the mental symptoms and the goitre appeared and disappeared simultaneously.

Dr. George Murray, in his Bradshaw Lecture of 1895, reported that out of 180 patients, three became insane, while ten others had hallucinations without other evidence of mental disorder. It should be mentioned here that mental symptoms, especially hallucinations, can be produced by the administration of thyroid extract to persons who are susceptible. No one type of mental disorder can be said to be characteristic of hyperthyroidism, but in the cases of severe grade agitated depression and confusion with hallucinations seem to be more frequent. One case reported by J. P. Grieve was of a severe form of mania which terminated fatally after six days of pyrexia. Three days before death the gland was so reduced in size that it could not be palpated. Four cases are reported by R. H. Steen, four making good mental recoveries, one after two years' duration, and all with a subsidence of the goitre symptoms. One patient died within a week after admission. Of the recovered cases, it is said that improvement was decided after the administration of adrenal extract. Gilmour gives an optimistic report of seven patients, four of whom recovered. He found a neuropathic history in most of the cases.

An interesting phase of the subject is furnished in a patient now under the writer's observation.

A young woman in whom the usual symptoms of hyperthyroidism had developed was operated upon for a partial removal of the thyroid gland. Six weeks after the operation she gave a remarkable recovery. Four years after the operation the patient heard of a friend who had undergone a similar operation and had suffered a return of the symptoms. Almost immediately the patient became depressed and weak until she should experience return of her temperature. She was examined by her physicians who were able to assure her that there were no indications of a recurrence of any signs of the condition. When search was made for another cause for her mental depression the examination revealed a laceration of the cervix which was repaired, and a displacement for which a shortening of the round ligaments was done. No improvement followed the operation and the patient continued depressed, became discouraged, refused to see her friends, and kept the florid time on the idea of the possible return of the goitre. About six months ago she suffered intensely from the effects of an abscess following the infection of a tooth. After the extraction of the tooth she became acutely ill with fever and rapidly passed into a typhoid state which lasted about four weeks, during which time she lost about thirty pounds in weight. For a few days she was stuporous, with difficulty in speech and swallowing. She slowly became clearer mentally, but still showed decided mental confusion. About six weeks later the confusion disappeared, but she had not returned to her normal mental state. She was apt to give way to violent attacks of temper, especially if crossed.

At the time of her admission to the hospital she presented a suggestion of an exophthalmos, which persisted although there had been no change in that respect in the past three months. There was a fine, scarcely noticeable tremor of the extended fingers which became more marked when she was much disturbed. There was also a fine tremor of the muscles about the mouth, likewise increased under emotion. The superficial and deep reflexes were all exaggerated. There were no disturbances of sensation and no vasomotor abnormalities had been observed. The heart showed some extension of the normal beyond the normal. There had been no tachycardia noticed at any time, the pulse rate being about 76 to 80 a minute, soft, but showing a quick rise under emotion. Urine was strongly acid, eighty per cent.; contained no albumin, no sugar, and no indican.

At the time of report the patient was in a state of depression with agitation only shown when she was addressed, when she usually bursts into a flood of tears, and at times almost a frenzy of grief. She was able at times to occupy herself with light work but seemed to be constantly engrossed with thoughts of herself and was apparently just on the verge of an emotional outbreak at all times. Occasionally she expressed indefinite fears of impending danger and seemed to be unable to realize that she was mentally ill. She was well oriented, had no fixed ideas and was not hallucinatory. The patient seemed to be more or less in constant fear lest she might do something which would bring her religion into question and thereby delay her returning to her home. On account of her marked emotional disturbance, she seemed confused; said that she could not make her mind up to do things and that she was unable to interest herself in anything.

The particular interest in this case centres about the fact that the psychosis developed in an individual who had been in good health for four years following a cessation of the symptoms of hyperthyroidism. If the gland was secreting in excess it was not sufficient to produce the usual subjective symptoms during that time between the thyroidectomy and the psychosis. Two factors, however,
entered to change the situation; first, a mental shock, the knowledge of the failure of a similar operation; second, a severe infection; both of these were operative in an individual with a predisposition, as shown by the prompt reaction in the form of mental depression following the shock.

There are at least three possibilities to be considered in the case, from the standpoint of the exciting cause. The present attack may be the beginning of a terminal mental condition—dementia praecox; it may be the forerunner of a return of the hyperthyroid syndrome, with mental symptoms exaggerated; it may be an infective exhaustive psychosis dependent upon the severe infection of the tooth abscess. I am inclined to believe that the last named is the chief exciting factor, acting in conjunction with the mental shock; also, it seems reasonable to believe that the psychosis might have occurred without the exophthalmic goitre. Whether the hyperthyroidism, shock or infection, or all three factors were responsible, the essential factor, however, lies in the predisposition in the form of a hypersensitive nervous mechanism.

Concerning the pathogenesis of exophthalmic goitre practically nothing from the causal side of the question is known. The four principal theories offered in regard to the etiology of the disease, three of which refer to the nervous system, are the following: 1. That it is a disease of the sympathetic nervous system. 2. That the seat of the disease is in the medulla oblongata. 3. That it is a neurosis. 4. That it is primarily a disease of the thyroid gland.

The cervical sympathetic was, and even recently, has been the subject of study. Lewin,6 in 1888, examined thirteen cases and found the cervical sympathetic normal, while others have reported definite findings. Belacso7 regards the thyroid enlargement as due to the dilatation of the large vessels which in turn is produced by stimulation of the vasodilators. The increased vascularity causes an increased secretion in the gland. Section of the sympathetic, he believes, prevents the exophthalmos. Jonnesco regards the struma as due to the permanent stimulation of the secretory fibres of the thyroid. Whichever theory may be correct atrophy is said to follow in every case of resection of the cervical sympathetic.

More recently Horau8 found a distinct thickening of the trunk of the right cervical sympathetic compared with the normal, and the cells or the ganglion had to a great extent disappeared. There was also found at the periphery an infiltration with newly formed connective tissue. A series of thirty-seven cases with changes in the nervous system was collected by Klein.9 Fifteen of the cases showed lesions in the neighborhood of the floor of the fourth ventricle. In four there were hemorrhages in the nucleus of the vagus. The tenth nucleus is regarded as belonging to the cell system of the intermediolateral tract which is the spinal localization of the sympathetic.

A. Ninan Bruce8 reported a case of myxedema following Graves's disease with mental symptoms leading to death from cardiac syncope, in which there were found hemorrhages into the nuclei of both vagi.

Although it must be admitted that the frequency of lesions in the central nervous system is, to say the least, worthy of attention, it must not be forgotten that the occurrence of hemorrhage can be explained by the mechanism of the altered vascular condition. A case has been reported in which enlargement of the thyroid gland suddenly developed in a middle aged woman with the physical signs and symptoms of hyperthyroidism, and at the same time paralysis of the third, fourth, and sixth cranial nerves. This would suggest a thyroid which had been secreting in excess for a time without producing symptoms severe enough to attract the attention of the patient. Later, a sudden exacerbation made itself manifest in the form of the above mentioned symptoms, the paralysis being the result of a sudden vascular disturbance or the sudden overwhelming of the nervous centres by the obnoxious materials. A remarkable peculiarity of the symptoms of Graves's disease is the variability in the severity of the symptoms, as is shown by the frequency of nervous and vascular crises. Dinkler10 states that the number and the severity of the symptoms in exophthalmic goitre suggest an anatomical basis for the manifestations on the part of the nervous system, but no constant lesions have yet been described, the various nervous changes reported having been more of the nature of complications or incidents. The case which he reported with autopsy and histological examination showed changes in the cerebral cortex, the ganglia of both sides, descending degeneration in the medulla and cord, and involvement of the facial and hypoglossal nuclei.

Of the nervous manifestations there were tremors of the hands, diminution of the electrical resistance of the skin, tendency to cry and to laugh, hasty speech and marked acceleration of all voluntary movements. The patient's entire character changed; there were hallucinations of all the senses, the patient becoming egoistic, disorderly, wasteful, and untidy. These mental symptoms were followed by twitching of the left arm, face, and leg, similar to that of chorea. The movements later disappeared and the side became hemiparetic, with added palsy of the tongue and bulbar symptoms. That author regards the cause of the disease as one of intoxication.

In a series of experiments upon animals by Tedesch11 in which lesions were produced in the restiform bodies, distinct symptoms of Basedow's disease occurred. Also it was found possible to reproduce those symptoms after they had diminished or disappeared, by producing a condition of hyperthyroidism. In thyroidectomized animals lesions of the restiform bodies did not produce the symptoms. In animals in which lesions of the restiform bodies and symptoms of hyperthyroidism were produced, removal of the thyroid causes the

11Rivista di patologia nervosa e mentale, vi, fasc. 6, June, 1902.
disappearance of the greater part of the symptoms. Some observers are willing to go so far as to state that the primary disturbance is in the cerebral centres controlling the nutrition of the thyroid and regulating the circulation. The author of this statement also says that in instances in which Gravez's disease exists there is almost uniform evidence of a neuropathic family history, and that these centres are constitutionally weak and the weakness is increased by emotional strain and infection. Dana reported two cases with autopsy with findings which led him to believe that the changes in the pneumogastric and other cranial nerve nuclei are important and constant lesions.

From this glance at the experience of a few careful observers it is evident that there are many features concerning the malady under discussion which point to a very close relationship of the nervous system, as most of the symptoms implicate the nervous mechanism. The question still to be answered is whether the disease is primarily one of the thyroid gland or of the nervous system. If the gland is the primary seat of the disorder, the nervous system suffers chiefly in the reaction. If the disorder is fundamentally one of the nervous system, the thyroid is apparently affected through its blood supply which has been altered by reason of a disturbance of the vasmotor apparatus. No matter which may be the original seat of disturbance there is doubtless established a vicious circle. The excessive secretion affects the nervous mechanism controlling the circulation in the organ, which in turn intensifies the state of hypersecretion.

There seems to be little doubt that certain individuals are by reason of inborn characteristics peculiarly susceptible to the effect of thyroid secretion. In fact, Kocke has shown that iodine applied to the skin may, in certain persons produce a condition which closely resembles Basedow's disease without producing the usual signs of acute iodism. Whether this is an accident or coincidence, there does seem to be an hyperthyroid potentiality which is present in certain individuals, coupled with a peculiar nervous instability, and this combination of predisposing factors is what presumably is needed for the establishment of the syndrome seen in hyperthyroidism. There are doubtless many individuals in whom the activity of the thyroid gland varies considerably at different times, just as under varying conditions any other epithelial organ may vary in activity. All of these persons do not present the usual symptoms of hyperthyroidism, for the reason that they are not sensitively reactive to the secretion of the gland.

There is an heredity chart on record showing a pedigree in which three sons and five daughters and three grandchildren were subjects of exophthalmic goitre.

Until more knowledge is obtained in regard to the action of thyroid upon persons who have neither hypothyroidism nor hyperthyroidism the pathological physiology will be still a matter of speculation.

Friends' Asylum, Frankford, Pa.

HIGH FREQUENCY CAUTERIZATION IN THE TREATMENT OF URETHRAL CARUNCLE.

By SOLOMON WIENER, M.D.,

Adjunct Gynecologist, Mount Sinai Hospital.

Urethral caruncle causes symptoms and gives rise to inconveniences of treatment out of all proportion to its small size and importance. The dysuria and tenesmus which so frequently accompany it may, by their psychic effect, render the life of a sensitive woman almost unbearable. Nor have we had a method of treatment which did not entail more or less discomfort, if not considerable pain, extending over a period of several days.

It is not feasible to twist off these little tumors because they have too broad a base. This applies whether the caruncle is only a granuloma, or a papillary angiomia, or a telangiectatic polyph; for all three of these lesions are connoted under the common term "caruncle."

The treatment herefore in vogue may be summed up in two words—cauterization and excision. The excision may of necessity be extensive enough to require the passing of one or more sutures, and the discomfort and pain of sutures at or within the meatus is too obvious to require further comment. Moreover they may necessitate rest in bed and the use of a permanent catheter.

The cauterization in vogue has been either chemical or by the actual cautery; the latter is the more efficacious method. Both give rise to a rather smart—reaction which may render the patient's life miserable for several days.

The work of E. Beer of New York in the treatment of bladder tumors by high frequency cauterization suggested to me that this might prove a satisfactory method of treating urethral caruncle; and such indeed it has proved beyond all expectation.

The technic is exceedingly simple: The caruncle and contiguous mucosa are anesthetized by the surface application of a five per cent, cocaine solution. An ordinary insulated wire electrode is used with a spark of medium intensity. The tip of the electrode is held about one eighth of an inch from the surface, of the growth, and the spark is passed successively over every part of its surface. The normal mucosa should be avoided. The entire application need not take longer than one minute. No pain whatsoever is experienced by the patient provided the cocaine has had sufficient time to act. There is no reaction after the effects of the cocaine have worn off; in fact, where dysuria and tenesmus are present, the very first urination following the treatment is less painful than those preceding it. Only very small carunculae can be destroyed at a single sitting. Usually two or three applications will be necessary. These had best be made at intervals of five or six days. In one case, of the flat angiomatous type, involving almost half the circumference of the meatus and extending a considerable distance upward along the posterior urethral wall, it was made wholly to disappear in three treat-

Beier, Edwin: Concerning the Treatment of Tumors of the Urinary Bladder with the Oudin High Frequency Currents, Annals of Surgery, August, 1911.
ments. This particular patient had been subjected to chemical cauterization by several physicians without any subjective benefit. There was marked diminution of her dysuria after the first application of the cauterizing spark. I may add that in all cases the mucosa remaining after the destruction of the caruncle was smooth and in all respects normal in appearance. There is nothing new claimed for this treatment; it is the same method which has been employed by dermatologists for a number of years in the destruction of cutaneous warts.

To sum up the advantages of this treatment for urethral caruncle, they are: 1. The ease and painlessness of its application. 2. The immediate alleviation of dysuria and tenesmus. 3. The absence of local reaction. 4. No necessity for confining patient to bed, as after excision and suture. 5. The complete restoration of the mucosa.

The success of this method has been so positive and pronounced in my hands that I am eager to recommend it to the profession.

CANCER.

By J. A. GUTHRIE, M.D.,
Porthsmouth, Va.
Surgeon, United States Navy, Retired.

Up to the present time, there seems to be no cure for cancer; therefore, my plan would be to discover a cause, and then work on the destruction of this cause, when, perhaps, we might establish a cure along this path of investigation. Most diseases are produced by germs; here is one that is apparently not.

We are chary of theorizing, and yet we know that the dreamer of yesterday, in his visionary outbursts, calling forth criticism, ridicule, and even persecution, has foreseen many of our commonplace topics of to-day. So expecting cautious analysis I shall launch my theory, notwithstanding.

A few years since we accepted as gospel truth quite a number of unchangeable chemical elements. One molecule magnified by comparison from the size of a billiard ball to that of the earth would show an appearance, say, of so many apples joined together, another so many pears, another so many marbles, another so many pith balls, ad infinitum. Now, we are guessing whether all of these elements are not one and the same, with, perhaps, variations in arrangement within the molecule. Suppose a molecule presents an appearance of a bushel basket filled with oranges, is there no reason why one of these atom oranges should not be divided and subdivided to infinity? Everything comprehensible through our five senses is by comparison. Something without beginning and without end cannot be impressed upon these senses. Suppose we say there is no beginning nor end to an atom, then we may vaguely conceive an entire solar system, ay! an entire universe wrapped up in a grain of sand. Some of this has already been threshed out by the radium maniacs.

Every individual cell of the human organism has, within itself, a guiding force, a microscopic soul, as it were. When many of these cells of the same natures congregate coordinately there is formed some distinctive organ, the liver, say.

These cells are likened to so many thoroughly disciplined armies, working, not through leaders, but by unanimous obedience to the wireless influence from the central powers. Now let some disseminator, some disturber, some sort of upsetting of the rank and file step in, and one of these little armies becomes a disorganized mob. A cancer is the corruption of cell elements of the skin, kidney, liver, stomach, or what not, from an organized and well disciplined army, into a riotous mob pushing, shoving, overturning (but forever increasing as mobs do) each other until destruction is the inevitable end of all. Make haste and harness radium so that we may send it into this mob, to take every individual cell by the scrub of the neck and throw it into a newly formed marching line. Or, sort out the dissenters, execute them, and build up a new army from the loyal remnant. The difference between a healthy cell and a cancerous cell element is the difference between the spick and span uniformed soldier with high ideals and the mud bespattered, torn, ragged, bleeding, dishevelled, involved in mental turpitude. The ancient idea providing roots for cancers, explanatory to the laity, meant the ramifications of stragglers, encouragers, and walking delegates from the riotous assemblage, scouting off and from the inflammatory mass.

It is impossible in many cases to get at these ramifications by means of so clumsy an instrument as the knife, therefore it is imperative that we enlist an agent, filmy, yet vastly more potent than surgical tools. In cutting, we of necessity destroy the good with the bad, endanger vital organs, and use a harsh method that often results, as in the case of a barn burned to destroy the rats therein.

When any topic, presented or discovered, warrants investigation—and surely that which is corroding and destroying human life should be found worthy—I believe, along every road, no matter how dimly perceptible, leading to this investigation, it would be well to send a scouting party, so to speak. Some will discover potent signs, some mysterious omens, and others will return hopelessly disappointed. Persistence, however, will win, so let us encourage every effort toward the right road.

In this age of radioactivity, microscopy, and the wonderful advances in photography, why not get at that cancerous tissue in its minutest detail? Another suggestion I would advance by way of simile, is the fact, that apparently there is an increase of vegetable cancers, along with the progress of civilization, due to the tampering with foreign flora by horticulturists, who wish to provide for the demands of acquired wealth, for instance. Experimenting in transplanting trees and shrubs to suit the tastes and desires of these, will show, to the close observer, a development not consistent with the original plans of Nature. Who cannot see the difference between the artistic lines, the fragrance, and the beauty of any wild tree, or flower, growing where it was planted, and one nurtured on forced draught, as it were, artificially, and far from its place of nativity? Wild animals in captivity do not thrive. Man is a captive, living within the prison walls of his clothing, his bed, and his food. In order to compromise, he must provide cures rather than prevention, which would exist primarily did he
but break through these walls and live the simple life, as shown to some extent, by the Arab of the desert, and certain tribes of Southeastern Europe. With our vast store of knowledge, and with the abandoning of our luxuries, how long and peacefully might we remain upon this dear old earth—our mother. But, when we disobey her mandates, surely we have sinned; and so, crop up the lowest forms of life,—the germs, to bring us to the state where we began—aons of time ago. Let us not go backward in vitality, while surging ahead intellectually; let us keep pace with both. Pleasure does not consist in charging through life, and sniffing for new joys; but, if we love Nature, and are kind to her, we shall find that her returned happiness, in the shape of perfect health, will constitute all the pleasures we need. Therefore, back to Nature, as far as is compatible with present conditions. To do this, in a nutshell, make laws to prevent the wholesale destruction of our five senses. Muffle all unnecessary noise, brilliant lighting, disagreeable odors, and touch not. Last and most important, eat and drink no poison, even though it should savor of the nectar and ambrosia of Olympus. With the revivifying of the sensory nerves, all the rest will sail in and become strong again. And then, we may expect to find eyeglasses, ear trumpets, and all such aids cast upon the trash heap. There will be nothing to cause irritation, and so we shall have no cancer.

**Prize Essays.**

Questions for discussion in this department are announced at frequent intervals. So far as they have been decided upon, the further questions are as follows:

**CXL.**—How do you treat the symptoms of senility, without organic disease, but showing approaching dissolution? (Answers due not later than November 15th.)

**CXLII.**—How do you treat frostbite? (Answers due not later than December 15th.)

**CXLIII.**—How do you treat chronic constipation? (Answers due not later than January 15, 1914.)

Whoever answers one of these questions in the manner most satisfactory to the editor and his advisers will receive a prize of $25. No importance whatever will be attached to literary style, but the award will be based solely on the value of the substance of the answer. It is requested (but not required) that the answers be short, if practicable no one answer to contain more than six hundred words; and our friends are urged to write on one side of the paper only.

All persons will be entitled to compete for the prize whether subscribers or not. This prize will not be awarded to any one person more than once within one year. Every answer must be accompanied by the writer’s full name and address, both of which we must be at liberty to publish. All papers contributed become the property of the journal. Our readers are asked to suggest topics for discussion.

The Prize of $25 for the best essay submitted in answer to Question CXXXIX was awarded to Dr. J. Walker Moore, of Philadelphia, Pa., whose article appears below.

**PRIZE QUESTION NO. CXXXIX.**

**TREATMENT OF CHANCROIDS.**

By J. Walker Moore, M.D., Philadelphia.

Chancroid is a specific, infectious, highly contagious disease caused by the bacillus of Ducrey. It is characterized anatomically by a local inflammation of the genitalia, proceeding to pustular formation and rapid ulceration; clinically, by a punched out ulcer, which has sharply defined and undermined margins, boggy or doughy in consistence, with a grayish sloughing base, discharging a profuse, purulent, foul, and autoinoculable material, pain to a considerable extent, and a tendency to the occurrence of certain complications, notably, bubo, phagedena; and if the lesion is subpreputial, phimosis and gangrene.

The infection is purely local to the parts upon which it develops and to the lymphatic vessels and ganglia in immediate anatomical association with the parts. Chancroid has its origin mainly, though not entirely so, from traumatism during sexual contact, thus accounting for the high proportion of genital lesions. There are a few reported cases of extragenital lesion, but these are rare. At times it is not an easy matter to make a diagnosis clinically between chancroid and other ulcers on the genitalia, particularly chancres. Thanks to our modern laboratory methods the debatable question can be settled within a few hours. The finding of *Spirocheta pallida* by means of dark field of illumination, or by Giemsa’s stain is diagnostic of chancre on the one hand, and the finding of Ducrey’s bacillus is diagnostic of chancroid on the other. We should always bear in mind the possibility of the ulcer being due to a mixed infection. Thus it is never safe to exclude syphilis until three or four weeks have elapsed.

The basis of treatment of a chancroid is something more than treatment of an ordinary ulcer, namely, cleanliness and antiseptics. We are here dealing with a microorganism, whose characteristics are essentially different from the ordinary pus producing bacteria, in that, 1, the epithelial cells are penetrated by the bacillus, which in turn causes coagulation necrosis, with subsequent erosion, possibly leading to phagedena; 2, the lymphatics are eager and do carry the organism to nearby glands, producing a complication (bubo) rather rare to pus organisms; 3, the power of autoinoculation is quite characteristic of the chancroid bacillus; thus the sore is usually multiple, rarely single, and occasionally with relapses. The multiplicity being due to the fact that the pus from the chancroid is acrid and irritating, thus rendering the epidermis softer (Morton), and by friction or otherwise, the epithelial barrier is made vulnerable to the attack of the microorganism. Suffice it to say that an abraded surface in a restricted sense is not essential for the entrance of the destructive foe. Like the pus producing ulcer, however, the chancroidal ulcer is superficial. Thus it would seem, the indications for treatment is to destroy the chancroidal character of the sore, and to transform it into a simple, noninfected ulcer when possible and no contraindications present.

The best means to this end are: Cauterization, cauterization with curettement, fulguration, excision, and radiant heat.

**Cauterization.—**Nitric acid and carbolic acid are the best caustic solutions. After the part has been rendered painless by local anesthesia, let me insist that a thorough cleansing of the entire penis should be carried out with green soap and water, and then
with warm bichloride (one in 1,000), and finally a rinse in sterile water. If the chancreoid is superficial, carbolic acid is indicated. Anesthetize with cocaine solution, ten to twenty per cent., and then apply carbolic acid with a glass rod or wooden applicator directly to the ulcer, making sure no part is left untouched. A neutralizing agent, such as alcohol, should be applied after one or two minutes’ action. Now, should the chancreoid be deeper and more extensive, with a pseudomembranous coating, nitric acid or the actual cautery should be employed. Local anesthesia should be accomplished by the hypodermic injection of eucaine. In case of nitric acid, it is well to protect the surrounding tissue with petrolatum, and neutralize the acid with sodium hydroxide after one to two minutes. The actual cautery is a most efficient agent, and is especially desirable in severe cases. The small point of the Paquin or galvanic cautery should be used and cautery carried a little beyond the diseased tissue. The only drawback being that at times it is objectionable to patients, and of course cautery of large areas means that the patient has to be anesthetized. Pedersen and Marsh, of New York, recommend the procedure used by Peterson, of St. Petersburg, in the early eighties. The procedure is as follows: The lesion is cleansed with water and gauze, cocaine is applied for five or ten minutes, then nitric acid is floated upon the sore, care being taken to work it well beneath the overhanging edges into all pockets; after the acid is allowed to remain two or three minutes, the lesion is wiped with blotting paper; then with a sharp curette the slough is thoroughly and deeply removed until clean, smooth, healthy looking tissue is reached. They further advised the ulcer to be touched up with ten per cent. silver nitrate, and wet dressings applied. This treatment is founded on sound reasoning, in that the affected area is rendered sterile, and by removing the necrotic tissue, healthy granulations make their appearance early. A rapid recovery is to be expected, as borne out by clinical results.

Excision.—The use of this procedure should be restricted. In the beginning of the chancreoid, even if there is doubt about the diagnosis, and if the lesion is limited to the foreskin, excision is an excellent procedure. It should be carried out by thorough cleansing of the parts, a hypodermic injection of eucaine around and beneath the ulcer, and painting the lesion with iodine solution, picking up the diseased area with a pair of mouse tooth forceps, cutting it out with scissors, and closing the wound with suture.

Fulguration.—The high frequency current has gained an important place in the treatment of certain pathological conditions, namely, cancer of the bladder, etc. It has been used and is still in use by a number of enthusiastic workers in the treatment of chancreoid. The results are not altogether edifying, but rather condemned by most genitourinary men. It acts through cautery of the tissue, but has no advantages over the simple caustics. In fact, the degree of cautery of the tissue is better controlled by the use of the simpler cauteries.

After the chancreoidal ulcer has been destroyed, the basis of treatment is cleanliness and antisepsis, namely, cleanse the ulcer with hydrogen dioxide and boric acid solution, Thiersch’s solution, or lead water and alcohol, cover with a gutta-percha tissue or paraffin paper, and retain with a bandage. The frequency of the dressings is to be carried out according to indications, usually three times daily.

There are certain contraindications for cautery that must be adhered to: When the sore is attacked by a high grade of inflammatory edema, prolonged immersion of the involved part in hot water, or in a hot bicarbonate of soda solution or, if you please, the entire body may be immersed in hot water, and the affected part sprayed with hydrogen dioxide and protargol one in 1,000, the dressings being kept constantly wet with the following solution:

- R Hydrargyri chloridi corrosivi, gr. ½ (0.01 grmme);
- Zinci sulphatis, ............ gr. ix (0.60 grmme);
- Acidii borici, ............... 3i (4.00 grmmes);
- Glycerini, .................. 3i (180.00 grmmes).

Misc. Fiat solutio.

Gauze wrung out of a solution of ammonium sulphochlhotate, one in 1,000, may be used (Martin). This should be applied three or four times daily. If the chancreoids are numerous and only a few are exposed, or if treated on the meatus, here conservative treatment is again indicated. Thus, the spots should be sprayed with hydrogen dioxide and protargol, one in 1,000, and a wet dressing of the solution given in the above formula applied. The prepuce may be stretched, and a thin layer of absorbent cotton, moistened with the solution, introduced between it and the glans penis. The patient should change the dressings every time he urinates or oftener. During the reparative stage when healing granulations make their appearance, scarlet red ointment or balsam of Peru, retained by cotton, is valuable. Schultz recommends basic fuchsin in this stage also. I have purposely omitted the use of dry dressings, the objection being that powders tend to cake and through the retention of secretion bubo is very likely to occur.

Vaccine therapy.—Herbst, Gatewood, Ito, and others have done considerable work along the line of preparing a vaccine for treatment of chancreoid. The results have not been gratifying. As yet, they have been unable to make a culture of the bacillus of Ducrey. Nevertheless, Herbst and Gatewood have treated a number of cases with autogenous vaccine, composed of a bacillus belonging to the pseudodiphtheroid group that they have isolated constantly from the sore, and at times found in pure culture. They report from this treatment alone a trifle less than thirty per cent. of cures.

Phimosis.—When the care of a subpreputial chancreoid has been neglected phimosis is a usual sequel. It is best treated by injecting with a flat balled syringe under the foreskin a protargol (one in 1,000) or weak sublimate solution; during the intervals of treatment the foreskin should be retracted if possible, care being taken that the mucous membrane is not torn, and a piece of absorbent cotton, saturated with Thiersch’s solution, the solution given in formula, or bichloride solution, put in place. The penis is then wrapped in wet dressings of bichloride, or lead water and alcohol. Now,
should the edema subside, thus permitting the fore-
skin to be retracted with ease, the parts should be
cleansed and the ulcer cauterized. If in spite of
careful treatment the edema progresses, surgical
treatment is indicated—cleanse the penis in the
usual manner, and split the prepuse upon the dor-
sum as far back as within one quarter inch of the
coronal sulcus. The chancreoids are exposed and
cauterized, as well as the fresh cut wound; then
treat as a common ulcer.

Paraphimosis.—This is relieved by cutting the
constricting band and cauterizing the chancreoids
and the fresh cut as well.

Phagedena.—This condition is usually due to
the low resistance of the individual attacked, as a
result of alcoholism, syphilis, tuberculosis, etc.
According to Scholz, in seventeen cases of pha-
gedena that came under his observation, the
minority showed weakness, debility, etc., while
the rest of them were of good physique and of
a robust appearance. He concludes, and rightly
so, that the extreme virulence of the streptoba-
cillus is a frequent cause. Here general and local
treatment is indicated. Rest in bed, soft nutriti-
tious diet, stimulants, and tonics, in the form of
iron, quinine, and strychnine are of prime im-
portance. Potassium Tartrate of iron, five grains given
every three hours, is said to be of great value
(Ricord). Opium is given to relieve pain. These
cases are often manifestations of late syphilis, hence
mercury and the iodides should be given a fair trial.
Locally, the actual cautery is essential and every
portion of the ulcer should be thoroughly cauter-
ized. If anesthesia is necessary, as is frequently the
case, gas or ether should be given. Good results are
obtained by hot baths, or sitz baths given four to
five times daily, or the patient may be allowed to
remain days or weeks at a time in the bath. A
powerful therapeutic agent that should be used only
in this variety of chancreoid is the x ray. Scholz
has achieved excellent results from the use of the
x ray treatment, and recommends the strength of
the current to be two milliamperes; distance from
the tube, six inches; duration of the treatment, ten
minutes; and exposure amounting to a half epy-
thema dose. The therapeutic action that the x ray
has in this condition is not definitely known, as
the rays are not germicidal. Scholz suggests the
curative value to be due to the peculiar property
of the rays to attack all pathological formation and
tissue in preference to healthy tissue. Inasmuch
then as the pathological tissue is attacked by the
rays and is caused to slough away, healthy granula-
tions gain a foothold and the ulcer soon heals.

Radiant heat has a number of advocates. The
pioneer of this treatment was August Bier. It was
first used in this country by Ruggler, of Rochester.
Scholz advises the treatment to be carried out as
follows: A daily exposure of from 10 to 20 minutes,
of a fifty candle power incandescent lamp, at a
distance of from 6 to 12 inches. He cites a case where
the chancreoid had resisted all forms of treatment:
after ten exposures he states that healthy granula-
tions appeared. After healthy granulations appear
in these ulcers balsam of Peru, scarlet red oint-
ment and basic fuchsin are indicated as healing
agents. The germicidal value of radiant heat is
explained by Scholz as being due to the action of
high temperature upon the bacillus of Durey. The
bacillus is killed at 122° F., and as I have pointed
out in the beginning, that the streptobacillus is
found very superficially located in the diseased
tissues, the thermic theory appears to be the correct
one. However, we must not lose sight of the value
of active hyperemia in this treatment, as has been
pointed out by Bier himself.

If, then, the virulent organism is attenuated by
heat or what not, active hyperemia plays an impor-
tant rôle in controlling the local condition.

Bubo.—The pathological process begins as a focal
necrosis in the centre of the node, and ends in a
complete resolution or more likely, if not properly
treated, in a breaking down and abscess formation
involving the surrounding tissues through direct
extension. A single gland is rarely involved per se,
usually several, and the stages of suppuration are
almost always at different intervals.

The streptobacillus has been found in the tissues
of an affected gland before suppuration had taken
place by Audrey, in the periglandular tissues by
Krepling. Ricord explains the virulence of a bubo
as due to external contamination, and believes that
if the incised bubo is well protected from the sec-
cretion of the chancreoid, the virulent condition
would not arise.

Sovinsky has pointed out that the bacillus of
Durey is carried to the glands and perishes there
after giving rise to suppuration. Thus, he asserts,
self-destruction explains why the bacillus is not
found in the bubo after maturation has taken place.
Early or latent virulence in a bubo may be explained
then by external contamination, but there are cases
on record where the bubo became virulent after
the chancreoid had healed. If we bear in mind that a
bubo is a polyadenitis, and these glands supplicative
at different intervals, we may understand how the
virulent organism may exist in a recently affected
gland before self-destruction has taken place.
If the ulcer is present, and we have reason to believe
that the bubo has been well protected from external
contamination, and latent virulence of the bubo
makes its appearance, I believe the lymphatics in
this case carry the bacillus to the noninfected bubo
and there set up an active process. Thus, I fail to
see the efficiency of injecting antiseptic solutions
into the glands to prevent suppuration, as recom-
manded by Wlduder, Lang, Cordier, and others.
Lehner advised puncture, expressing the retained
pus, covering the opening with a moist dressing,
and changing the dressing frequently. Mosetig, Moor-
hof, and Lasser advocate the removal of the infect-
ed glands if they are deep seated. Total extirpa-
tion of the inguinal glands, however plausible it
may seem, is to be feared, owing to the fact that
permanent edema (elephantiasis) may be the result,
as pointed out by Lasser, Virchow, Neisser and
others. From Sovinsky's experimental deductions,
and from the pathological process that takes place,
I can see where no benefit can be derived in early
suppuration of the inguinal glands from the use of
small incisions, evacuations of pus, and the injec-
tion of iodoform and glycerin into the cavity. If a
single gland is affected, the procedure is admirable, but if there is present a polyadenitis, the method is usually an endless procedure.

In nonsuppurating adenitis, rest in bed, cold applications, evaporating lotions, moderate pressure obtained by shot bag, sandbag or by a bandage and compress, as recommended by Kollmann, and revulsion produced by blisters, give the best results. Cumston states that a bubo can be aborted before suppuration appears, if a blister is applied. After suppuration is well established, the best results are obtained by thoroughly cleansing the penis and surrounding parts, protecting the field of operation, making free incision, evacuating the pus, curetting or dissecting out the partially broken down remains of the glands, and packing with iodoform gauze, renewing the dressing daily.

**Episcopal Hospital.**

**Dr. F. D. Austin, of Charlotte, N. C., says:**

In the treatment of chancroids it must be remembered that we have to deal with a severe local infection, that is autoinoculable, and very destructive to the tissues, which must be immediately and rightly handled.

The main indications are: 1. To destroy the infection, which is due to Ducrey's bacillus; 2. To prevent the autoinoculation; 3. To heal the ulcer; 4. To treat the complications as they arise. To destroy Ducrey's bacillus, there is perhaps nothing as reliable as a thorough cauterization of the ulcer. First touch each ulcer with a little pure phenol and neutralize with a little alcohol for its anesthetic effect, then swab out the ulcers with pure nitric acid. This will burn quite a little for a few minutes, but the action will soon subside. To prevent autoinoculation, we must keep all the ulcers as nearly free from discharge as possible, using frequent baths of one in 2,000 bichloride of mercury solution, prevent the ulcers from touching the healthy skin at any point, and change the dressings every three or four hours.

The most satisfactory local dressings used in my office are as follows:

- **B** Five per cent, solution of tincture of iodine in liquid petrolatum, -------120 c. c.  
  Sig.: Apply to ulcers on a little absorbent cotton every four hours.

This is not at all irritating, and the tincture of iodine will greatly aid in the destruction of the infection.

Another old dressing, and a very good one, is as follows:

- **B** Spiritus terebinthinae, -------2 c. c.; Emulsions iodoformi (five per cent.), -------58 c. c.  
  M. Sig.: Apply locally on a little absorbent cotton.

The spirits of turpentine will deodorize the iodoform pretty well and render it less objectionable.

Or,

- **B** Iodoformi, -------30 grammes.  
  Sig.: Use as a dusting powder after each bath.

The odor of iodoform is very disagreeable, and the tincture of iodine will take its place very nicely.

Or,

- **B** Lotions nigris, -------120 c. c.  
  Sig.: Apply locally every three hours on absorbent cotton.

After three or four days of the foregoing treat-
and the majority of the best men, condemn it, therefore, I do not use this method at all.

Phimosis is another complication that must be relieved when the chancre is located under the prepuce. A simple dorsal incision through the prepuce will suffice.

Paraphimosis, sometimes though very rarely, occurs as a complication of chancre. This is best treated by hot compresses and gentle reduction, but if it cannot be relieved a dorsal slit will take care of this also.

Chancroids sometimes assume the phagedenic condition. If they do, the foregoing treatment, together with systemic tonics, etc., will suffice.

Serpiginous chancroids are treated likewise.

(To be continued.)

Therapeutic Notes.

Treatment of Fissured Hands.—Brocq, in Nouveaux remèdes for June 8, 1913, is credited with the following combination, a few drops of which are to be well rubbed over the hands morning and evening:

R.  
\[
\begin{array}{l}
\text{Aqua rose,} \quad 3i\text{iss (100 grammes)}; \\
\text{Glycerini neutralis,} \quad 3i\text{ (30 grammes)}; \\
\text{Acidi tannici,} \quad 0.5\text{ grammes.} \\
\text{Misc.}
\end{array}
\]

Before retiring there should be applied to the affected parts either pure hydroxyl wool fat or one of the following preparations:

I.  
\[
\begin{array}{l}
\text{Vanillini,} \quad 0.5\text{ grammes;} \\
\text{Olei rose,} \quad \text{gr.} \quad 0.5\text{ i;} \\
\text{Adipis lane hydrosi,} \quad \text{gr.} \quad 5\text{ (5 grammes).}
\end{array}
\]

M. Ft. unguentum.

II.  
\[
\begin{array}{l}
\text{Mentholis,} \quad 1.5\text{ grammes;} \\
\text{Phenylis salicylatis,} \quad \text{gr.} \quad 2\text{ (2 grammes)}; \\
\text{Olei olive,} \quad \text{gr.} \quad 0.5\text{ i;} \\
\text{Adipis lane hydrosi,} \quad 3i\text{ss (50 grammes).}
\end{array}
\]

M. Ft. unguentum.

Treatment of Intestinal Toxemia.—A. L. McIlroy, in the Glasgow Medical Journal for September, 1913, states that the first essential in taking up the treatment is to have the mouth put in a healthy condition, the teeth being gone over by a dentist and the gums disinfected with tincture of iodine or by ionic medication. As for the diet, dry meals are often of benefit, copious draughts of water being taken, however, between meals and in the early morning. A plentiful supply of fat in the form of butter is of value. Green vegetables are difficult of digestion. In some cases of marked toxemia, even of the chronic variety, it is necessary to put the patient on a milk diet for several weeks. In severe forms, too, it should be borne in mind that small and frequent meals are preferable to large meals at long intervals.

Exercises to strengthen the abdominal muscles are of great value, e. g., lying flat on the floor and raising the trunk to a sitting posture without the aid of the arms; lying flat and raising the legs perpendicularly; standing straight with the feet close together and bending forward until the fingers nearly or quite touch the ground. These exercises are best performed after the morning bath, and each should be repeated about a dozen times. Abdominal belts or binders are of benefit in many cases, their object being to prevent the downward pressure of the viscera and lend support to the abdominal walls.

In women of the hospital class, the author advises a broad binder of new flannel, carefully applied with safety pins while the patient is recumbent.

In regard to medicinal treatment, the writer lays stress upon the avoidance of frequent doses of purgatives in chronic cases, though occasionally calomel and other drugs have to be given for diagnostic and surgical purposes, as well as in acute conditions. In cases of obstinate intestinal stasis, he has had excellent results from the following procedure. On rising in the morning the patient takes a tablespoonful of pure liquid paraffin, about half an hour or more before breakfast. This acts as an intestinal lubricant, and prevents septic absorption. After breakfast the patient must go daily to stool whether defecation takes place or not, and in time will find that a regular bowel movement results. Sometimes an additional dose of the liquid paraffin is given at bedtime, if required.

Natural mineral waters may be given, and in cases of fecal accumulation, a small enema of olive oil at bedtime is of benefit. The author has at times employed pituitary extract for chronic constipation, and has found it of value, whether given hypoderminally or by mouth.

Where an obvious lesion is present, or where all other measures have been tried without success, due consideration should be given to the benefit to be gained by short circuiting operations between the small and large intestine, or even the removal of part of the latter.

Subcutaneous Injections of Oxygen in Acute Psychoses.—Toulouse and Puillett, in Bulletins et mémoires de la Société médicale des hôpitaux de Paris, July 24, 1913, report excellent results in cases of acute mania, mental confusion, and manic depressive psychosis, such as commonly result from physical and mental overstrain as well as infections —especially in the puerperal period—by subcutaneous oxygen injections. A remarkably prompt effect upon the mental excitement and confusion in these patients was observed, a tendency to quietude and return of mental lucidity being apparent on the day of the first injection, and improvement being so marked on the succeeding days as to result in a complete cure of cases otherwise destined to follow a protracted course. Two illustrative cases are reported, both in puerperal women, but one showing excitement while the other was depressed, in which the oxygen injections clearly brought about recovery in a few days, although the trouble had already persisted for some weeks. The measure was also tried in other forms of insanity, including dementia, to overcome excitement and insomnia, and was found to bring relief in most instances.

The apparatus used consisted of two communicating bottles, one filled with water and connected with an atomizer bulb, pressure upon which forced the water into the second bottle, into which oxygen had previously been passed. The filling of the second bottle with water forced the oxygen in it through a rubber tube and hypodermic needle into the tis-
sues. This device permits of exactly regulating the speed of introduction and amount of gas used. The oxygen is washed by passage through water at the time of introduction into the apparatus. Over one hundred injections were given without a single case of infection. The amount introduced was from 120 to 150 c. c. at the first injection from 200 to 250 c. c. at the second, and 500 c. c. at subsequent injections. The injections were administered directly under the skin on the external aspect of the thigh. In some instances, when the 500 c. c. dose had been reached the interval was lengthened to forty-eight hours. The two thighs were injected alternately. The time consumed for an injection was ten to fifteen minutes for a 500 c. c. dose. The slight pain resulting from the injections disappears very soon, but the skin becomes quite red and there develops a subcutaneous emphysema, at times affecting the whole external surface of the thigh and disappearing in from six to twelve hours. No other local or general reaction was in any case witnessed. In addition to the favorable effect on the nervous system, however, there was noted a marked and prompt increase in the appetite—with normal digestion and absence of either diarrhea or constipation—as well as a tendency to increased body weight.

Treatment of Gonococcal Arthritis.—A. S. Solovtsova, in *Semaine médicole* for September 17, 1913, is credited with having obtained good results in gonococcal arthritis by application of compresses moistened with the following solution:

- **R** Acidi salicylici, 3v (20 grammes);
- Alcoholis, 3vi (200 grammes);
- Olei ricini, 5v (20 grammes).

M. et ft. solutio.

In a young man who had been suffering three weeks from gonococcal arthritis of the left knee, with rather high fever, and in whom sodium salicylate, bromides and iodides internally, as well as methyl salicylic, alcohol, and tincture of iodine, externally, had failed to bring lasting relief, application of the solution here formulated caused marked improvement within twenty-four hours, and in five days the patient was able to stand on the involved limb. The joint returned to its normal size, the fever subsided and the patient was able to leave the hospital in a week. When swelling of the other knee, with pain and difficulty of motion, later appeared, the solution again caused the trouble to disappear in a few days. The solution causes redness, and after three or four applications, an actual burn of the skin. A bland ointment should therefore be used in the intervals.

Use of Formaldehyde in Anal Surgery.—

Robert Engel, in *Progrès médical* for April 26, 1913, warmly recommends the employment of dilute formaldehyde solutions in the postoperative treatment of anal and perianal affections. For all patients operated upon for anal fistula or hemorrhoids he orders two sitz baths, each of twenty minutes' duration, containing two per cent, of commercial formaldehyde solution, to be given daily. The strength of the solution is then gradually increased to eight per cent, which is generally attained on the tenth day after the operation. At first, the patient's bowels are kept inactive with opium pills. Under the formaldehyde treatment local infective processes rapidly subside and as a rule the wound heals before the patient has been to stool. In cases of fistula, the gauze wick draining the canal is removed by the patient while in the first bath; a fresh, dry dressing is afterward applied. At the second bath the drainage wick need not be disturbed at all. After Whitehead's operation, the formaldehyde baths gave very satisfactory results. The gut sutures around the anus were absorbed less rapidly, moreover, than is usually the case, this completely preventing loosening of the anal mucous membrane and its ascent into the rectum. The postoperative treatment of fistula in ano was also often markedly shortened by the formaldehyde baths. The baths cause at first a slight stinging sensation, but this soon disappears.

**Treatment of Neuralgia.**—A writer in *Paris médical* for May 31, 1913, recommends the following liniment for neuralgia:

- **B** Chloroformi, 3ss (20 grammes);
- Aetheris, 3ss (30 grammes);
- Alcoholis, 3i (90 grammes);
- Camphorae, 5ii (8 grammes);
- Turpentinei, M. et ft. 530 (3 grammes).

M. et ft. linimentum.

A square piece of flannel should be moistened with the liniment, placed over the seat of pain, and covered with some impermeable material.

In pain at the anus, not accounted for by a fistula or rectal lesion, the following liniment may be rubbed over the part several times a day:

- **B** Extracti belladonae foliorum, 3ss (2 grammes);
- Chloroformi, 3ss (3 grammes);
- Glycerini, 3ss (15 grammes).

M. et ft. linimentum.

In peri orbital neuralgia and ophthalmic migraine, Galewowski uses the following ointment:

- **B** Mentholis, gr. xi (0.85 grammes);
- Cocaine, gr. iv (0.25 grammes);
- Chlorali hyoscini, gr. iv (0.25 grammes).

Sig.: Rub ointment over the seat of pain and cover with oiled silk.

**Treatment of Chronic Spastic Constipation.**—

Pissaff, at a recent meeting of the Paris Société de Thérapeutique (*Paris médical*, July 5, 1913), asserted that, clinically, patients with chronic constipation due to spasm may be divided into two groups, viz., 1. those who experience no discomfort and in whom the spastic state is the result of excessive local irritability, and, 2. those who do suffer and are the subjects of spasm arising through nervousness and general irritability. In eighteen patients of the first group, the following combination of remedies uniformly gave permanently successful results:

- **B** Bismuthi subcarbonatis, 3ss (2 grammes);
- Magnesii ossi, 3ss (1 grammme);
- Belladonnae foliorum, gr. 1/2 (0.02 grammme).

Sig.: One powder to be taken a half hour before each meal.

In the second class of patients, on the other hand, these remedies were of but little use, bringing about only temporary improvement in three patients and failing to benefit the others.

DRUG SUBSTITUTES AND PEDDLERS.

The evils of substitution have reached a point that may justly be called appalling in the absolutely conscienceless manner of their exploiting the retail pharmacist and dispensing physician alike. The physician suffers in reputation and pocket more than the retailer, for he is unfamiliar with market quotations and lacks the business instinct which would arouse his suspicions at unusually low rates. The pirate manufacturers who make substitute tablets are, moreover, clever enough to include in their formula a small dose of the genuine drug so as to meet the qualitative analysis which is likely to be the sole reliance of even the best qualified general practitioner. There is little if any excuse for the retailer, for the salesman’s visit is preceded by a circular from the fraudulent manufacturer, the terms of which are sufficiently explicit to permit of no doubt as to the base nature of the product. Moreover, many of the retailers purchase by mail order. The plain hints as to the fraudulent nature of the goods are omitted from circulars sent to physicians. Ignorant of the fraud to which he is a party, both when dispensing and when prescribing, the physician wonders why the prescribed drug fails to manifest its usual action; he is led to increase the dose, to try something else, even to doubt his diagnosis.

He is likely to lose his grasp of the case and the confidence of his patient who seeks medical aid elsewhere.

Physicians are awaking finally to this kind of fraud and, to protect themselves, are not unlikely to equip and maintain pharmacies of their own, which could be easily conducted at a small but satisfying profit. Such a course would deal the death-blow to the present sort of combined pharmacy and novelty store and make every druggist choose whether he will be a professional pharmacist or a mere tradesman without either professional responsibility or prestige. Is there a doubt in the mind of any thinking pharmacist as to the cause of the springing up everywhere of the new “chain stores”? Both physician and patient have, rightly or wrongly, confidence in the immense resources of these establishments and believe that they are supplying genuine and pure drugs at reasonable prices.

The products of every legitimate manufacturer have suffered from this illegal and outrageous substitution, but especially the modern synthetic preparations, most of which represent invaluable and now indispensable additions to the materia medica. They mark a distinct evolution in modern pharmacological research, and every pharmacist should encourage these advances in pharmaceutical chemistry, since it is his duty to be equally interested with the physician in the stay of disease and the relief of suffering. It is beginning to look as if the tremendous strides of modern biochemistry would soon force a parting between the present type of druggist and a more highly educated successor who will rank, in training and responsibilities, as an absolute equal of the physician. Meanwhile, however, the retailer must preserve the finest type of moral conscience, while the physician forced to dispense must learn that probably only the highest priced and most carefully sealed and safeguarded packages contain pharmaceutical products worthy of his attention and confidence. He can begin at once by buying nothing from the door to door peddler.

These peddlers, to put it mildly, are quite irresponsible even when they are honest, while among them are many individuals of the lowest type, who combine with their sales to physicians the vending of morphine and cocaine to habitués. It is to the activities of this class that we owe the persistent spread of drug habits in spite of the most stringent State and Federal legislation. By refusing to purchase of peddlers, the physician can practically put them out of business, for their underground traffic would perish with their ostensible occupation. The physician is in the gravest danger in accepting goods from these men who generally “represent” some manufacturing pharmacist without ethical or
THE DIAGNOSIS OF CARDIAC TUMORS.

Textbooks are singularly deficient in information concerning the various forms of tumor which may occur in the heart. This, doubtless, is due in part to Oppolzer's misguided remark that these neoplasms have no clinical interest because it is hardly ever possible to recognize their existence during life. Clinicians have thus been led to overlook cardiac growths in the differential diagnosis of heart disorders, with the result—suggested by the relatively large number of tumors found post mortem, the existence of which had not been suspected,—that deaths occur, at least in a small proportion of cases, which might have been prevented by timely treatment. Cardiac gummata, which are promptly amenable to appropriate measures, afford a typical example of this fact; even sarcoma might, perhaps, be successfully mastered by means of Coley's fluid. These facts clearly sustain the view that in the study of organic disorder of the heart, cardiac tumors should always be included among the possible causes. Especially does the utility of this course assert itself when the diagnostic features brought out recently by clinicians who have followed it are added to those previously at our disposal.

The signs of cardiac tumor vary obviously with the location and size of the growth, but all cases may present more or less prominently the symptoms common to the more frequent forms of heart disease; precordial pain, dyspnea, vertigo, edema, syncope, murmurs, etc. More or less suggestive signs begin to appear, however, when the location of the growth is such as to interfere directly with cardiac functions. Thus, as recently noted by Horneffer and Gautier in three cases of tumor of the left auricle, the dyspnea differed from that observed in the average case of heart disease in that it was particularly severe; it was also accompanied by distressing paroxysms pointing to temporary obstruction, more or less complete, of the orifice, sufficient at times to cause brief periods of syncope. These also occurred when the position of the body was abruptly changed. A systolic murmur or duplication of the second sound, with irregularities of rhythm and marked inconstancy of heart findings, were also noted. Bard has observed a suggestive phenomenon, viz., that when the jugular and esophageal pulse tracings are compared—the jugular representing the activity of the right auricle and the esophageal that of the left auricle, the region most frequently the seat of primary cardiac growths,—distinct differences between them may be observed. The esophageal tracing shows a much less pronounced postsystolic rise than normal, the curve at this point attaining a level much lower than that of the presystolic and systolic elevations, whereas normally the opposite is the case. This is due to rigidity of the posterior wall of the left auricle owing to its infiltration by the tumor. Another abnormality is the marked diminution in the presystolic rise, contrasting with the normal rise seen in the jugular tracing and referable, therefore, to the right auricle. The history likewise affords considerable aid in such cases. Thus, as shown by Huchard and Fiessinger, the occurrence in old syphilis of gradually progressive dyspnea, edema, and cyanosis, often with a small, rapid, high tension pulse, is very suggestive of cardiac gumma, which appropriate measures soon overcome where cardiac therapy on the usual lines will prove absolutely sterile in results.

On the whole, it is clearly evident that Oppolzer's advice to ignore cardiac neoplasms as clinical entities should no longer be followed, and that the only course warranted, nowadays, is to trace carefully to their source all signs that the diseased organ affords.

ETIOLOGY AND TREATMENT OF BERIBERI.

Although beriberi is, strictly speaking, a tropical disease, it is nevertheless one which may at any time fall under the observation of the physician in seaport towns of the temperate zone. This fact, together with our new policy of national expansion into tropical regions, make it desirable that the profession at large should maintain an active interest in the researches conducted under the auspices of the Philippine Bureau of Science into the etiology and treatment of this disease. For many years there has been a practical consensus that the multiple neuritis which is the concomitant of beriberi is in some way related to the ingestion of rice. The older textbooks speak of the disease as being caused by the ingestion of spoiled rice. The later ones lend themselves to the view that hand
polished or highly milled rice is responsible for the condition. The truth appears to be established that in the external layers of the rice grain there exists a substance, the absence of which is in some way connected with the development of beriberi. One of the proximate principles of this substance has been isolated by Young and is variously known as Young’s basic substance or “beriberi vitamine.” The researches of Vedder and Williams seem to indicate that this basic vitamine has a specific action in preventing the development of the paralytic symptoms of “dry beriberi,” whereas another substance in the pericarpal layers of the rice grain is specific against the edema and heart failure arising in connection with “wet beriberi.” Whether the disease is a purely nutritional one dependent upon the absence of phosphorus-containing vitamines in spoiled or highly polished rice, or whether it is due to an infection against which the vitamines act as specific antidotes are points which the researches of Vedder and Williams (Philippine Journal of Science, June, 1913) do not appear to have satisfactorily solved. Their investigations have resulted, however, in the finding of what amounts to a practical cure for the disease. For although its essential causation remains unknown, the fact has been demonstrated that the administration of unhydrolyzed extract of rice polishings is curative for the symptoms of dropsy and cardiac failure that are encountered in some forms, whereas Young’s basic vitamine promptly relieves the paralysis which is sooner or later developed in all chronic forms.

**HIPPOCRATES AND MODERN MEDICINE.**

Dr. Eduard Baeumer, of Berlin, describes in an essay, *Der Hippokratismus*, some of the remarkable conditions in the medicine of the present time and points out the necessity of returning to the principles of Hippocrates.

The disciple of modern medical science, entering into practice armed with a great amount of knowledge and fairly trained in exact methods, finds sooner or later that scientific glory is not all sufficient, not all reliable. He finds that one thing alone is essential—to know how to heal—to become an adept in the art of healing. All knowledge and all science are of value only as a means in the service of the healing art; science is never the art itself.

The wonderful progress made in the natural sciences during the nineteenth century has brought to the front great changes in medicine. With new methods of investigation discoveries after discoveries have been made, and the beneficial influence of natural science cannot be overestimated. Facts innumerable have been disclosed—so many, indeed, that it has become impossible for one man to grasp them all; so many that even a specialist cannot master his entire specialty, and specialisms of specialisms have arisen. The whole body of investigators exalting themselves throughout the year are bound to make new discoveries and to publish them; hence a surprising growth of medical literature. And who is able at present simply to survey the valuable publications, not to speak of the ability to separate the wheat from the chaff?

Hippocrates was the first to lay down the basis and the principles of the healing art for all time, and Hippocrates repeatedly in the course of history has been the salvation of medicine. The genuine Hippocratism lives in eternal youth, because the observations of Hippocrates, free from theories, are drawn from the inexhaustible well of Nature, and retain, therefore, their value independent of even the most progressive phase of medical development. Hippocrates inspires with fresh and youthful ardor the researcher who has entered into his spirit, because he does not demand faith in scientific dogmas, but, on the contrary, incites step by step to sober observation. It is true we possess a greater fund of facts and a more intimate knowledge of anatomy and physiology than he, but nevertheless we can learn from him. He knew no medical “science,” he only knew the art of healing.

When we take up the study of Hippocrates we are surprised how modern everything sounds, for we have entered on this study with the idea in our minds, “What can this old Greek teach us, who are so far advanced in knowledge and technic?” We forget that it was Hippocrates who established the fundamental principles of the healing art. The principles and foundation of our art undergo no change, no evolution; hence the eternal youth of Hippocrates. Hippocratism has had, and always will have, an historical mission. He liberated medicine from dogmatism and faith in authority even during the Middle Ages.

What is the significance of Hippocratism in modern medicine? The division of medicine into more and more specialties must lead to untenable conditions, and Hippocratism alone will have to be our salvation.

**SYMPATHETIC ASEPTIC POSTOPERATIVE FEVER.**

In discussing the results achieved by anoc association anesthesia before the New York Society of Anesthetists Dr. George W. Crile, of Cleveland, pointed out that most of the so called aseptic post-
operative fever is essentially a matter of pure fright. In fact, he asserted and gave evidence that a temperature chart of the friends or family of the patient would not infrequently show cases of “aseptic postoperative fever” on the part of relatives who had not been on the table at all and whose rise of temperature was due solely to sympathetic fright. In one case reported the patient operated upon presented no rise in temperature, whereas the sister, merely from sympathetic fright, showed a temperature quite in keeping, in its rise, duration, and decline, with what has hitherto been known as “aseptic postoperative fever.”

Doctor Crile’s study of surgical shock and its consequences has a wide application in medicine outside the realm of pure surgery. The illustrations which were shown by him on the occasion referred to of the effects of fright on brain tissue and the apparently logical deduction which he draws regarding so called aseptic postoperative fever, convey a significant warning to physicians as well as surgeons, for the physician not infrequently occupies a position where, unless he exercises tact and discretion, he may administer a shock or cause a fright which will have an important bearing upon the physical as well as the mental poise of the patient.

CLOSURE OF THE OPENING PRODUCED IN PARACENTESIS ABDOMINIS.

E. Lebrun, in Quinzone thérapeutique for September 25, 1913, refers to the fact that all the measures commonly employed to arrest the flow of ascitic fluid after tapping the abdomen not infrequently fail. Lately he has been applying a Michelin clamp over the trocar opening in every case of paracentesis, with uniformly successful results, subsequent drenching of the dressings and bedclothes with the fluid being always prevented. A trocar of rather large calibre is used, in order to evacuate as much fluid as possible at the first tapping. As the trocar is withdrawn, the margins of the opening are held together between the thumb and finger of the left hand, tincture of iodine applied, and the previously prepared clamp attached, including as great a thickness of the local tissues as possible. A sterile dressing is then applied, next a pad of cotton wool, and finally a moderately tight bandage. Later the clamp is removed. In one of the author’s cases subcutaneous infiltration of the lower abdominal wall and scrotum took place, but this is an occurrence not uncommon after any form of paracentesis, even where nothing obstructs the continued flow of fluid through the trocar opening. Furthermore, such infiltration automatically brings into play a therapeutic influence sometimes purposefully availed of, viz., autoserotherapy. By laying hold of the skin deeply before the clamp is applied, subsequent infiltration is almost always avoided, and the flow to the exterior invariably.

Changes of Address.—Dr. S. R. Klein, to 2321 Cambrelling Avenue, the Bronx, New York.

Southern Surgical and Gynecological Association.—The annual meeting of this association will be held in Atlanta, Ga., December 16th to 19th, under the presidency of Dr. John Y. Brown of St. Louis, Mo., Dr. W. D. Haggard of Nashville, Tenn., as secretary.

Harvey Society Lectures.—The fifth lecture in the course will be given on Saturday evening, December 13th, at the New York Academy of Medicine, by Dr. Rufus Cole of the Rockefeller Institute for Medical Research, his subject being Pneumococcus Infections and Lobar Pneumonia.

Cholera in Rumania.—According to official reports of the United States Public Health Service, dated November 28, 1913, there were reported in Rumania 22 cases of cholera and 28 deaths from the disease during the period from October 23 to October 29, 1913, making a total of 5,656 cases with 2,908 deaths from the beginning of the outbreak to date.

Meetings of Medical Societies to Be Held in Philadelphia during the Coming Week.—Monday, December 8th, Northwestern General Hospital Medical Society; Tuesday, December 9th, Pediatric Society; Wednesday, December 10th, Philadelphia Surgical Society; Thursday, December 11th, Polyclinic Ophthalmic Society; Psychological Society; Friday, December 12th, Northern Medical Association.

The New Montefiore Home.—More than five thousand persons attended the dedication of the group of new buildings of the Montefiore Home, in East 210th Street, New York, on Sunday, November 30th. There are nine large buildings, which will accommodate nearly seven hundred patients. The total cost of the new buildings with equipment was nearly $2,000,000, and the expense of maintenance will amount to about $300,000 a year. Dr. Siegfried Wachmann is medical director and general superintendent of the institution.

The Mütter Lecture to Be Given by Doctor Coffey.—The joint course of special lectures being given in Philadelphia this season under the auspices of the Rush Society, the College of Physicians of Philadelphia, the University of Pennsylvania, the Philadelphia Pathological Society, and the Mütter Museum, includes the Mütter Lecture, which will be given on the evening of December 12th, at 8:30 o’clock, at the College of Physicians, by Dr. R. C. Coffey, of Portland, Ore. His subject will be the Surgical Treatment of Chronic Constipation.

Legislation on Mercurochloride Tablets.—There are now three bills before Congress intended to regulate the sale of mercurochloride tablets. One of these requires that the tablets shall be green in color and cubical in shape. The latest bill introduced is that proposed by Senator Gallinger, of New Hampshire, who is a physician. This bill requires that all tablets of mercurochloride shall be flat, triangular, or three-cornered in shape, colored blue, and dispensed only in blue or amber colored corrugated bottles, conspicuously labelled “Poison” in red letters. An ordinance prohibiting the sale of these tablets has been proposed by the Board of Aldermen of Baltimore. The matter is under consideration by the Health Commissioner Leaderle, of New York, who has received various suggestions, but has not yet decided what action he will take.

The Death of Dr. Louis Peiser.—At a meeting of the Medical Board of the Bronx Hospital and Dispensary, held November 11, 1913, it was unanimously

Resolved, That we deeply deplore the unexpected death of our colleague and fellow member, Dr. Louis Peiser. We recall his cheery and happy disposition, his unfailing courtesy, his constant endeavor for the uplift of his profession, and his scientific interest therein. We shall miss his sage counsel and sincere willingness to bear his share of the work in the building up of our institution, and we tender our most respectful condolences to his bereaved family. Be it further

Resolved, That a copy of these resolutions be sent to his family and the medical press and be entered in our minutes.
Personal.—Dr. George W. Outerbridge has been selected to fill the vacancy on the visiting obstetrical staff of the Maternity Hospital of Philadelphia caused by the recent resignation of Dr. L. J. Hammond, a member of the staff since 1893.

Dr. J. Solis-Cohen was elected an honorary member of the Philadelphia Laryngological Society at its November meeting.

The Bay Ridge Hospital.—The directors of this hospital have acquired title to a parcel of land situated at Ninety-second Street and Seventh Avenue, Brooklyn, on which it is their intention to erect a modern hospital, large enough to accommodate one hundred patients, at a cost of approximately $150,000. Dr. Robert E. Coughlin is chief of clinic and president of the medical staff; Dr. Bruce G. Blackman is treasurer of the board of directors; Dr. Frank E. Stoney, corresponding secretary, and Dr. Joseph W. Malley, recording secretary.

New Building Assured for St. Giles Hospital, Brooklyn.—In the last hour of a ten day campaign to raise $100,000 for the erection of a modern hospital building for the House of St. Giles the Crippled, $12,000 was subscribed, bringing the total amount up to $104,460.50. The trustees of the hospital give the greatest credit for the success of the campaign to Dr. Burr Burton Mosher and Mr. A. E. Hoffsmmer. The House of St. Giles the Crippled is the only institution of its kind and exclusive devoted exclusively to the care of crippled children, and its present accommodations are wholly inadequate to the demands made upon it. Brooklyn and Long Island finding it necessary to call upon Manhattan to treat two thousand of their children annually. The crippled children themselves gave $500 toward the fund.

The Safety and Sanitation Conference.—In connection with the International Exposition of Safety and Sanitation conference will be held in Ruxton Hall, Chemists' Building, 50 East Forty-first Street, New York, on Wednesday, Thursday, and Friday, December 10th, 11th, and 12th, under the auspices of the American Museum of Safety. There will be two sessions daily, in the mornings and afternoons, one for preliminary papers, and a second for special papers, the last being devoted exclusively to the care of crippled children, and its present accommodations are wholly inadequate to the demands made upon it. Brooklyn and Long Island finding it necessary to call upon Manhattan to treat two thousand of their children annually. The crippled children themselves gave $500 toward the fund.

Street Accidents in New York.—Thirty-eight persons were killed in the streets of New York by automobiles during the month of November, according to the report of the National Highways Protective Society. The number is three more than the highest previous month of which there is a record, and 17 more than for November, 1912. Of the 38 persons killed, 15 were children under sixteen years, and 23 were killed by trolleys, as against 13 for the same month last year, and 11 by wagons, as compared with 22 for November, 1912. The number injured by automobiles was 115, as compared to 50 by trolleys and 24 by wagons. The total number of persons killed in New York by all kinds of vehicular traffic was 39 in November. During the first three days of the past week more than six hundred drivers of automobiles were arrested in New York for fast or careless driving. Fines of $50 to $25 were imposed.

To Unity Federal and State Laws on Food and Drugs.—For the purpose of ascertaining and suggesting means for the reconciliation and unification of Federal and State laws on food and drugs, a committee composed of members of the National Conference on Uniform State Laws for Purity of Articles of Commerce is now engaged in a consideration of this subject, with a view to making recommendations to this end at the next annual conference of the commissioners on uniform laws. At a meeting of this conference held in New York on November 21st and 22d, a number of representatives of various organizations presented the results of their investigations and proposed remedies for variances and inconsistencies in the Federal and State laws. These suggestions were discussed and formal action was taken. It is understood to be the purpose of the committee to prepare recommendations to be submitted to the commissioners at their next meeting.

Physiological Albuminuria from the Military Medical Standpoint.—Hecker says that although the last word had not been said in the teachings concerning physiological albuminuria, still it can with certainty be stated that the excretion of albumin over a period of many years, recurring regularly under certain conditions, is compatible with general health, and there is no reason to couple this occurrence with the fear of a severe kidney lesion. From this viewpoint the author believes that the 25,000 men who are now barred from service could be restored to the German army.

Epidemic of Paratyphoid in the Infantry Regiment No. 78 in Osnabrück.—R. Otto proves on the basis of bacteriological and serological investigation that the infection of the men with para- typhoid bacilli and their poisons was due to the meat consumed on a certain day. The slaughtered animal was positively healthy, but the butcher also sold meat from imported sources, so it is possible that the healthy meat was infected by the imported meat by being carried in the same meat containers.

Pure Cultures of Smallpox Germs.—Forney freed the raw lymph (Rob lymph) of calves of all foreign bodies by agitating it with ether. The effectiveness of the lymph is in no way lessened by thus treating it with ether. In contradistinction to the glycerin lymph used at the present time, the bacteriological sterile ether lymph can be kept for a long time, even in high temperatures. The virus of smallpox can be cultivated from one reagent glass to another, but loses a little in virulence in the passage; these cultures may be obtained from the real pox as well as from the cowpox. "Microsoma variola seu vaccinia" is the active agent, because it is the only living organism in the effective cultures; it resembles the smallest forms described by many authors under diverse names.

The Danger of Pestilence in War.—Landgraf discusses the military medical measures taken in war to prevent the appearance of pests and the prevention of their spread after introduction.

October 13, 1913.

Late Abscesses after Appendicitis.—E. Melchior's observations give a typical example of the oft recurring phenomenon in surgery, namely the latent infection. These late abscesses presented a prognostically good course.

Therapy of Chronic Anacidity.—M. Hirschberg found that in the therapy of the anacid stomach affections, a whole series of factors must be considered, to none of which can be ascribed the sole curative action, but that all, in combination, bring about the successful issue.

Recurrent Eclampsia.—C. Holste reports this case, which although it came to autopsy, did not offer important data for the solution of the clinical picture of this condition. In a similar case of tendency to eclampsia, as this reported case, the author
advise resection of the tubes to sterilize the patient in order to make subsequent conception impossible.

Sero logical Pregnancy Reaction after Abderhalden.—F. Ebeler and R. Lomberg found in one hundred cases of pregnancy the positive ninhydrin reaction. It is also present in nongravid woman and therefore at the present time, with the incomplete technic cannot be regarded as specific. They believe, however, that the method will gain a permanent position as a diagnostic aid in clinical routine.

The Dangers of Mercurial Treatment and Their Prevention: A Case of Mercurial Vaginal Gangrene.—W. Wolfenstein shows that mercury under certain conditions, and irrespective of the method of application or of the preparation used, is a dangerous poison. In every case where symptoms of incipient intoxication appear, the administration of mercury is to be immediately discontinued. The observance of careful rules of administration and of all contraindications will make it possible to avoid the severe intoxications or at least reduce them to a minimum.

The Nephritic Heart Anomalies in Scarlet Fever, and their Treatment.—Adolf Baginsky, in many cases of the combined symptoms of the usual kind, with dilatation of the heart and failing compensation, with hydrops, high fever, and severe dyspnea, has applied the "cold sweat packing" with actually life saving results.

Resistance of the White Blood Corpuscles.—A. Fraenkel demonstrates by experiments on the resistance of the blood cells, that the small and the large lymphocytes possess a stronger resisting power than the others; he concludes from this an eminent biological significance for these cells.

Vaccination Therapy of Cancer.—A. Pinkuss and Kloninger express the hope that vaccination therapy may be able, through the administration of suitable vaccines in combination, to prevent the recidives far from the field of operation or of metastases. The results from mesothorium radiations in recurrences in the field of operation have given rise to this hope.

The Immunization of the Blood against Septic Disease.—P. Krehl observes that women who have, recently or long ago, undergone mercurial treatment have a normal puerperal or postabortive period, notwithstanding the fact that there were present extraordinarily unfavorable hygienic conditions. Systematic animal experiments show that mercury injected intramuscularly, as a prophylactic measure in the form of hydrargrum benzoicum, renders the organism immune for streptococcus infection, in insufficient doses the infective process was at least limited to a local process. Small and delayed injections of mercury did not help the organism in its fight against the infection.

CORRESPONDENZBLATT FÜR SCHWEIZER ÄRZTE.

October 17, 1913.

Röntgenograms of Pulmonary Tuberculosis.—Hans Staub presents a beautiful series of twenty röntgenograms illustrating lesions in the lungs, but to abstract his paper is not feasible.

Clinical Experiences in the Treatment of Pneumothorax in Pulmonary Tuberculosis.—O. Amrein and F. Lichtenhahn report twenty cases. They say that when the cases are not too far advanced, and the lung can be totally compressed, operation is usually followed by immediate disappearance of fever and general improvement. Failure occurred in three of their cases, one because of the onset of empyema, another because of inanition and intestinal tuberculosis, a third because of the subsequent appearance of the disease on the other side. They find that to carry out this treatment without danger the aid of the x rays is always necessary.

ZENTRALLBLATT FÜR CHIRURGIE.

October 18, 1913.

Gangrene of the Feet in the Balkan War.—A. Welcher and Lothar Dreyer refer to previous publications on the subject and maintain that the gangrene was not caused by frostbite. Welcher saw 115 cases in which the men had suffered a week or two before from a typical attack of cholera, dysentery, or diarrhea. In forty-five other cases it developed in men who had just recovered from typhoid fever. At another time he saw many cases of frozen feet, and the symptoms in these cases were materially different from those of the gangrene following intestinal trouble. In the second Balkan campaign the cholera arrived during the summer, but no cases of gangrene came to his knowledge. Dreyer seems to think freezing played a part, favored by their foot covering, but that it was largely due to malnutrition and intestinal disorders.

October, 1913.

Angioma of the Choroid.—Robert Salus reports a case of this nature and concludes that the early anatomical condition of an angioma of the choroid is characterized by a number of changes that seem to belong quite regularly to the development and extent of this form of growth. These are: A high degree of cystoid degeneration of the retina, confined to the region of the tumor, leaving the surrounding parts of the retina nearly or quite normal and capable of function; the limitation of the detachment of the retina to the region of the tumor and its extremely slow increase, although the opposite would be expected from the nature of the growth; the appearance of adhesions between the outer layers of the retina and the subjacent tissue without any signs of inflammation; the appearance of a more or less thick and dense connective tissue or epithelial layer separating the tumor from the interior of the eye.

Chancro of the Conjunctiva of the Upper Lid.—Theodor Fischer-Galati reports a rare case of chancro of the transition fold of the conjunctiva of the upper lid, met with in a man twenty-six years old. The infection may have been carried by kissing, or by the finger.
PARIS MÉDICAL
November 1, 1913.

Diuretics.—A. Pic classifies diuretics according to the form of diuresis they induce, viz., as hyduretic, producing a watery urine, chloruretic, increasing the elimination of sodium chloride more than that of the other urinary constituents, and azoturetic, increasing especially nitrogen elimination. In the first group belong water, infusions of various drugs, such as uva ursi, juniper, scoparius, etc., and several sugars; in the second, theobromine, theophylline (dimethyl xanthene), caffeine, calcium chloride and sodium chloride; and in the third, squill, formic acid and its salts (to be used only with great circumspection), and sugars, such as lactose, which though acting chiefly as a watery diuretic, brings about an abundant excretion of urea. The diuresis brought on by water is accompanied by intracellular changes, with vacuole formation, showing heightened activity on the part of the renal cells. The colder the water ingested, the greater is the diuresis. Distilled water yields a pronounced diuresis, contrary to the view formerly held. Sugars probably act both by an osmotic influence and by excitation of the renal epithelium and are especially effective in oliguria due to infections, combining cardiac stimulation with the other effects. In doses of from 0.5 to 2 grammes, calcium chloride causes a parallel increase in the quantity of urine and its chloride content, while the urea and phosphates remain unaffected; it can be of considerable value clinically. Sodium chloride injections increase chloride elimination only in small doses, in isotonic or hypertonic solutions, and where no edema-producing nephritis exists.

Treatment of Amebic Lesions with Salts of Emetine.—C. Dopper advises that not less than 0.04 gramme of emetine hydrochloride be injected at a dose in amebic dysentery, and that the drug be continued for some days after clinical recovery, to prevent early recurrence of the trouble. Doubt is still permissible as to whether emetine can completely sterilize the human organism of amebae, some patients presenting in the stools, after apparent clinical cure, amebic cysts upon which the drug does not seem to have much destructive effect. The fact remains, however, that emetine is more effective in arresting the dysenteric paroxysm than any other agent.

Pituitary Extract in Obstetrics.—Metzger agrees with the conclusions of previous writers as to the indications for pituitary extract, but advises that the fetal heart sounds be kept under careful observation during its use, slowing and irregularity of the beats, owing to excessively prolonged uterine contractions, having been so marked in four of his cases as to necessitate rapid delivery with forceps.

Action of Sodium Chloride on Renal Secretion. —H. Roger reports experiments in rabbits which showed that whereas intravenous injection of large amounts of isotonic sodium chloride solution leads to an increase in the amount of water in the system, injection of hypertonic solutions causes dehydration. The hypertonic solutions are strongly diuretic, but as the water passes through the kidneys more easily than the salt, the urine at first secreted is relatively poor in salt. Later, however, after the preliminary paroxysm of polyuria, the proportion of salt in the urine may rise to as much as 5.40 per cent. Where the amount of salt introduced has not exceeded four grammes per kilogramme of body weight, it is completely eliminated in twenty-four hours, or even, an excess may be eliminated over that introduced; where the amount introduced equals or exceeds five grammes in each kilogramme, chloride retention results. Toxic effects depend on the amount of salt retained in the system rather than on the amount originally given.

Galyl in the Treatment of Syphilis.—P. Troisfontaines administered galyl, or tetraoxydiphosphamo diarsenobenzene, which contains 35.3 per cent. of arsenic, to twenty-one syphilitic patients. Three to four intravenous injections of from 0.2 to 0.55 gramme were given at intervals of from four to seven days. The drug dissolves readily in water to which a small amount of sodium carbonate has been added. The larger doses—0.4 to 0.5 gramme—gave results but slightly better than the smaller amounts. Chancre promptly healed; secondary eruptions faded in twenty-four hours and disappeared in four or five days, with the exception of the papular form, complete eradication of which required at times eighteen to twenty days; mucous patches disappeared with extreme rapidity, while tertiary ulcers were also observed uniformly to heal. On the whole, Troisfontaines considers galyl a practically nontoxic, well borne drug, at least as efficacious as salvarsan and other similar arsenicals. Trial of galyl on a larger scale is advised.

November 5, 1913.

Diagnosis of Gastrointestinal Ulcerations by Study of the Feces.—R. Goiffon points out that Weber’s guaiac test for blood in the feces at times yields a negative result in spite of the presence of a considerable amount of blood, and advises the routine employment of Meyer’s phenolphthalein test,—with the fecal material greatly diluted to avoid excessive sensitiveness of the reaction—as a check for the guaiac test. As regards albumin in the feces, he strongly recommends the test recently described by Triboulet, which is advantageous in being simple and in demonstrating albumin only where the latter exists in a pathologically significant amount. It is performed by adding to diluted feces in a test tube a few cubic centimetres of a solution of 3.5 grammes of mercury bichloride and one cubic centimetre of acetic acid in 100 cubic centimetres of distilled water. After from fifteen minutes to an hour, instead of a division of the fluid into a lower sedimentary and upper turbid layer, there is observed merely a clot formation, with clear fluid between the retracted portions of the clot, the presence of albumins—not mucin or nucleoalbumins—is shown. Such albumins always indicate tuberculous, cancerous, or other variety of ulceration in the intestine, and further, tend to show that the trouble is in the large bowel, since albumin from the stomach or small intestine is digested before evacuation.
The Antigen in Wassermann's Reaction.—A. Desmoulière describes the preparation of an antigen which he has found far more sensitive than those now in general use. Dried and powdered human liver tissue—not necessarily from a congenital syphilitis—is completely extracted with ether. One gramme of the residue is macerated three days at 37° C. with twenty c. c. of absolute alcohol, and filtered after cooling. To ten c. c. of the fluid thus obtained is added 0.1 gramme of pure, powdered cholesterol, which is brought into solution by incubating at 37° C. for a few hours. This antigen must be kept in darkness at a temperature of about 15° C. A one in fifteen dilution of it, to the amount of 0.3 c. c., is used in performing the Wassermann reaction. The latter should always be preceded by a simple test, which Desmoulière describes, to determine the proper amount of complement to be used. After this, only two tubes need be used in carrying out the reaction. An exact scale of the intensity of the reaction is afforded by comparison with a solution of acid fuchsin and picric acid. Thus performed, the Wassermann reaction will give identical results in the hands of different observers; will permit of diagnosticating syphilis even in the first few days of the disease, a result not attainable with the old Wassermann technic, and will demonstrate syphilis in cases in which the old Wassermann technic gives only doubtful or negative results (including cases of inherited syphilis). In a number of cases wrongly considered cured—as shown by subsequent recurrence—after salvarsan treatment, the author's Wassermann reaction was positive at a time when the reaction as ordinarily conducted was negative. Desmoulière also presents a formula for an artificial antigen, i. e., one not made from liver tissue, which he found in about two hundred trials to give results equivalent to those obtained in the Wassermann reaction with syphilitic liver antigen as ordinarily prepared.

BRITISH MEDICAL JOURNAL.
November 8, 1913.

The Rational Treatment of Chronic Bacillary Dysentery.—Leonard Rogers says that the pathological findings in this form of the disease consist mainly in lesions of the lower portions of the large intestine. Here extensive, depressed, serrigenous ulcers are found on a thickened intestinal wall. Between these are small islets of mucous membrane. The diagnosis of the condition is sometimes very difficult, on account of the clinical similarity between it and the chronic form of amebic dysentery. If, however, a few doses of emetine are not followed by marked improvement it is almost certain that the condition is of bacillary origin. On account of the site of the lesions drugs given by mouth do not come into contact with the diseased tissues in concentration sufficient to have any material remedial action. The ideal way would seem to be to treat the condition from below. Experiments with a number of antisepsics and germicides, carried on with cultures of the Shiga bacillus, both in broth and in saline solutions containing organic matter, led Rogers to the conclusion that those drugs which were not precipitated by the broth or the salt would be the most effective clinically. His subsequent trials in the treatment of a number of cases have confirmed this conclusion. The most satisfactory drug so far tested has been albarin or silver gelatose, in solution of about one in 500, injected by rectum and retained as long as possible. His results with this method of treatment have been very good, but he has encountered some cases in which little or no relief was afforded, indicating that the method is only relatively successful.

Acute Dilatation of the Stomach during Operation.—W. G. Richardson had just completed an operation for the repair of a perforated duodenal ulcer, and had begun to suture the abdominal incision, when the upper abdomen began to enlarge. The enlargement proceeded so rapidly that in half a minute the stomach was bulging into the wound. The dilatation of the stomach continued until that viscus was like a drum. The veins on the wall of the organ became very much engorged. There was no distention of the duodenum or of any other portion of the intestinal tract. The contained gas escaped with a rush through a tube which was passed into the stomach through the mouth. The distention was immediately followed by a marked contraction of the stomach, which became no larger in diameter than the large intestine. The venous engorgement also passed off. At the same time respiration, which had been greatly embarrassed, became easy and thoracic, and the complexion became pink. The dilated pupils contracted. The entire series of phenomena lasted less than five minutes. It is to be noted that the operation had been accomplished with little disturbance of any of the abdominal organs except for the slight handling of the duodenum itself in the course of its suture.

Chronic Interstitial Nephritis in Children.—Hugh Barber's first patient was a boy, seven and a half years old when first seen in 1905. At that time his growth was obviously stunted, and, although no definite symptoms were complained of, an analysis of his urine showed it to be of low specific gravity 1.010—and that it contained albumin, but no casts. There was no change from that time until 1911, the urinary findings remaining almost constant. Though fourteen years old, he seemed to be only about seven or eight, and was only four feet tall. His genitals were undeveloped and there was no growth of hair on the body. The urine then ranged from 1.003 to 1.066 in specific gravity, and contained one part of albumin per mille. There were still no casts. He was pale, had no edema, and there were no signs indicative of arteriosclerosis. His complaints were of intense thirst and polyuria. He had occasional attacks of headache and vomiting. He died when fifteen years old, the albumin having gradually increased to two parts per mille. On post mortem examination the kidneys were found to be very small, and presented both gross and microscopic features typical of advanced chronic interstitial nephritis. His sister began to have thirst and polyuria, with urine of low specific gravity and containing albumin, when twelve years old. She also seemed considerably undeveloped. She is still living, three years after first observation, and has all of the typical features presented by her brother. Neither of the children had any of the usual children's diseases. The striking feature in the etiology of these two cases is found in the fact that their mother was physically much overworked.
during the time that she was pregnant with these children. Her other children were all well at the time of the writing of these notes. One other case is reported, coming from another family, and presenting symptoms similar to those already recorded. Post mortem examination in this case confirmed the diagnosis. It is suggested that in the cases of the two children from the same family, the kidneys may have been damaged in the intrauterine life of the children through toxic absorption from the mother, who was not well at the time of these pregnancies.

Micrococci in the Blood and Cerebrospinal Fluid of Two Cases of Mania.—William Boyd and G. L. Brunton report the isolation of micrococci from both blood and cerebrospinal fluid in each of two cases of acute mania. The organisms did not correspond in either case with any of the known varieties, and were not alike in the two cases. Both organisms were diplococci; one Gram negative, the other strongly positive.

Treatment of Gonorrheal Epididymitis by Bier's Method.—A. C. Wilson first passes a strip of lint bandage around the cord on the affected side, just above the testicle. This is continued along the median raphe between the two testicles, and over it is applied a piece of fine rubber tubing which is then tightened until no pain results after its application. It is held by artery clamps, and allowed to remain in situ, usually for an hour on the first day, increasing up to as long as eight hours a day toward the end of the treatment. The treatment causes immediate relief of pain, such that the patient is often enabled to return to work in less than two days after the first application. With this treatment it is well to continue all of the usual measures employed. The method not only relieves the pain of the disease, but shortens the course of treatment from the usual ten days to two or more weeks down to from four to ten, or twelve days. It is applicable to all chronic cases and to most of the acute ones.

Diagnosis and Treatment of Epidemic Bacillary Dysentery.—J. Graham Willmore and A. Harold Savage, contrary to the generally accepted views, find that it is neither practicable nor necessary to identify the precise strain of infecting bacillus, and that many cases harbor more than one of the types. It suffices to plate out cultures from the stools and to test the colonies which conform culturally to the general class of dysentery organisms by means of agglutination reactions. This greatly simplifies the diagnosis and shortens the time required before the treatment can be instituted. In their hands the most satisfactory results of treatment have been secured by the injection of large doses—up to 120 c. c. of polyvalent serum, made from cultures of all four of the dysentery bacilli. Such treatment has reduced the mortality from about seventy per cent. to between twelve and twenty-one per cent. In their experience the use of the serum is not fraught with danger, as has been stated by others to be the case.

Phlebotomus Fever and Dengue.—C. Birt calls attention to the very great similarities existing between certain cases of yellow fever, dengue, and phlebotomus fever. All three diseases are known to be transmitted by mosquitoes or by the sand fly; all are caused by viruses which are filterable through bacteria proof filters; all are most prevalent in the tropical regions; all occur both epidemically and sporadically; and the symptoms of mild cases of yellow fever may very closely resemble those of either of the other diseases, while dengue and phlebotomus fever are strikingly alike in symptomatology. It is also known that the prevalence of dengue is often parallel to that of yellow fever. Between these three diseases, otherwise so similar, the most striking differences are to be found in the length of time which an insect remains infectious after it bites an infected person, the number of days after infection before a person can infect an insect, and the variety of insect which most commonly carries each disease. In spite, therefore, of the other features, which tend to suggest that the three diseases may be more closely related etiologically than has been thought, it is not probable that there is any identity of causative agent.

Gonorrhea Phylacogen.—L. W. Harrison, from an experience of sixteen cases, finds that this remedy is "chiefly successful in relieving pain." In practically all of his cases of epididymitis, and in the single case of gonorrheal arthritis, pain was more or less ameliorated after the first injection. In most, however, the pain returned within a few days, although the phylacogen was still being administered. In only one case did the use of the phylacogen seem to hasten recovery—the case of arthritis. It had no influence whatever upon the cases of gonorrheal urethritis. The doses used by Harrison were large, and the subcutaneous, intramuscular, and intravenous methods of administration were all tried. The injection was very often followed by a reaction. In the majority of cases the pain was very great at the site of injection, when this had been subcutaneous or intramuscular. In some of the cases of intravenous injection there was a marked constitutional reaction. The temperature of one patient rose to 105.6° F. after an intramuscular injection. The pain was so severe in a few of the cases that the patients expressed themselves as preferring the suffering from the epididymitis to that from the phylacogen. By complement deviation tests, Harrison has not been able to prove the presence in the blood of gonorrheal patients of any antibody to phylacogen.

Epidemics of Poliomyelitis.—Paul B. Roth reports an epidemic of six cases of poliomyelitis which involved five small villages, separated from one another by not less than two and a half miles. The individuals involved in the outbreak were never in direct communication with one another, nor was there any traceable evidence of the intervention of any possible carrier. All of the cases occurred within a little more than a month in the summer. The one common feature among the several cases lay in the environment, all patients residing in the immediate vicinity of barns or stables where the fly, Stomoxys calcitrans, was very abundant. On the basis of the findings of Rosenau, confirmed by Anderson and Frost, to the effect that these flies are capable of carrying the virus of poliomyelitis,
and in the absence of all other means of transmission, Roth believes that this insect was the means of the spread of the disease in this epidemic. Quite different are the observations made by George Jubb from an epidemic of eight cases in an urban locality in which there had been no previous case of the disease. Jubb believes that his first case originated from a donkey which was brought in from another region, and which was badly infested by lice. It seems possible to trace all of the succeeding cases to direct or indirect contact with the first patient, or with subsequent cases. It is interesting to note, however, that after the first case appeared there was an interval of about a year before the remainder of the patients became infected. It is believed that this is due to the harboring of the virus by a brother of the first patient, who acted as a carrier, himself not becoming infected.

Polyvalent Tuberculin.—Halliday Sutherland prepares a polyvalent tuberculin of the following composition in each c. c.; Tuberculin Koch, 0.025 c. c.; bovine tuberculin, 0.025 c. c.; vacuum tuberculin, 0.025 c. c.; bovine vacuum tuberculin, 0.025 c. c.; tuberculin T. R., 0.05 c. c.; bovine tuberculin T. R., 0.05 c. c.; bacillary emulsion, 0.033 c. c.; bovine bacillary emulsion, 0.033 c. c.; polygenous bacillary emulsion, 0.034 c. c.; T. O. A., 0.35 c. c.; and P. T. O., 0.35 c. c. This mixture is diluted in series, each dilution being one tenth the strength of the preceding. Injections are made as usual, using the largest dose possible without causing a severe reaction. It is deemed absolutely necessary to record the patient’s temperature at least three times daily. The type of temperature curve obtained after the injection is held by Sutherland to be of the utmost prognostic and therapeutic value: 1. An immediate rise of temperature with a fall by crisis is the mildest reaction and calls for an increase in the dose for the next injection. 2. A delayed rise with a fall by crisis comes next in degree and calls for the repetition of the same dose. 3. Next in severity is an immediate rise with a fall by lysis, which calls for a reduction of the dose by one fifth. 4. A delayed reaction with a fall of the temperature by lysis demands a reduction of the dose by one half. 5. A progressive rise of temperature with a fall by crisis is the indication for a reduction to one tenth of the dose. 6. Lastly, a progressive rise and a fall by lysis requires the withholding of tuberculin, and is indicative of a very bad prognosis. These preparations and methods of dose determination have given very promising results in a series of 137 ambulant patients.

The Diagnostic Value of Abderhalden’s Method in Carcinoma.—R. St. Leger Brockman has obtained positive results in twenty-five undoubted cases of carcinoma, and negative in twenty non-carcinomatous cases, using the dialysis technic of Abderhalden.

Indian Medical Gazette.

October, 1912.

A Surgical Curiosity.—J. Bodley Scott reports a case in which a young man fell from a tree so that a piece of bamboo penetrated his thigh. The piece of bamboo was pulled out, and the wound healed at first, but later an abscess formed and broke, leaving a sinus from which pus and urine escaped for two years. At the end of that time a stone could be detected in the bladder both by a sound passed through the urethra and by a probe passed upward along the sinus at the apex of Scarpa’s triangle. Lateral lithotomy was performed and a large stone was removed, in the centre of which was a small piece of bamboo. The patient recovered.

BOSTON MEDICAL AND SURGICAL JOURNAL.

November 20, 1912.

Observations on Summer Diarrheas in Children during 1911.—Arthur I. Kendall, Alexander A. Day, and Edward P. Bagg say in conclusion: The striking fact brought out by the summer’s work is that in every case of infantile diarrhea studied (with the exception of the few fermentative diarrheas) there was a general conformity in bacterial type of the intestinal flora, which was uniformly proteolytic in character. This proteolytic flora forms a striking contrast to that of normal children of similar age, in which the putrefactive activities are minimal. Superimposed upon this proteolytic background various well known intestinal pathogens may stand out conspicuously. In the past the isolation of such organisms has sufficed to establish the diagnosis; it now appears that such is not necessarily the case, inasmuch as one or more of them may be present without the production of noteworthy symptoms. On the other hand, cases are met with in which these organisms cannot be found, yet show blood, pus, and mucus in the stools, and severe toxemia. In these latter cases the flora has been found to be proteolytic in character.

Saprophytism, Parasitism, and Pathogenism.—Arthur I. Kendall defines these terms, which he says are frequently confounded. Saprophytic bacteria are those subsisting upon dead organic matter. Parasitic bacteria are those living on living organic matter. Pathogenic bacteria are those which produce disease in living plants and animals. The writer speaks of three babies found to harbor typical dysentery bacilli, and other bacteria commonly regarded as pathogenic, yet presented no characteristic symptoms. They were taken to be cases of improper feeding, and the discovery was the result of the policy of examining each patient to determine the bacteria in the intestinal flora. Two of the patients were twins. The cases were under observation for several weeks and successive isolations of the bacteria were made. Aside from a wrong bacterial diagnosis, which is unlikely, there are three possibilities to explain the situation: 1. The patients were immune both to the dysentery bacilli and the other associated pathogenic bacteria; in that case the babies were bacilli carriers. 2. The cases were mild ones of dysentery; in that case the associated organisms were innocuous or at best very inactive. 3. The organisms were nonvirulent, in which case they might be assumed to be innocuous for the average nonimmune into whom they might find their way. The evidence for each possibility is given. No definite decision is made.

Observations on Summer Diarrheas in Children during 1912.—Arthur I. Kendall and Alexander A. Day say that this summer was note-
worthy from the bacteriological point of view for the large numbers of cases of severe diarrheas apparently of gas bacillus origin.

**Hospital Management of Contagious Diseases,** by D. L. Richardson.—See this Journal, for July 5th, p. 41.

**Transplantation of the Testicle,** V. D. Lespinasse describes previous attempts at transplantation and his own experimental work, reports a human case, and presents the following conclusions: Transplantation of the testicle is a perfect operation in frogs and chickens; spermatogenesis and sexual characteristics are preserved. In guinea pigs, rabbits, and dogs the results are variable. In the two human cases which have been tried to date the one with the bloodvessel anastomosis was certainly a failure as far as spermatogenesis is concerned, but the interstitial cells may be, and probably are present. In his own case the result clinically has been absolutely perfect; the man has regained his sexual powers completely, both as to desire and ability to perform. Furthermore, these powers have remained present for two years.

**Operative Treatment of Hallux valgus and Bunion,** J. D. Singley states that the method of Fowler, modified by himself, possesses certain advantages which may be summarized as follows: 1. The incision is in a place where, even on theoretical grounds, it cannot be objectionable. 2. It affords a much better exposure of the diseased ends of the bones than any other method, and permits accurate shaping of the new articular surfaces. 3. The joint is opened on the outer side, dividing the shortened external ligament; an important step in avoiding recurrence. 4. Ankylosis is prevented, and a new joint formed by the interposition of a fatty fibrous flap.

**Local Specific Therapy of Infections,** Simon Flexner (second Harben lecture) presents the results already obtained by this method, derived partly from experiment and partly from experience with human cases of disease, and relating chiefly, but not exclusively, to the infections of the membranes of the central nervous system which have formed the starting point of the studies on which the method has come to rest. Among the points brought out are the following: The accumulated experience of the past six years has demonstrated the value of antinemococcus serum and made necessary a revision of certain notions concerning its action. Formerly no fundamental biological distinctions were made between meningococci; now differences in power of resistance to solution by immune serum are being recognized. Under the influence of the serum the diplococci come, as a rule, to be more and more within the leucocytes, and as recovery from the meningitis progresses, even though no antiserum has been employed, a corresponding phenomenon is noted. Indications exist, however, that certain examples of epidemic meningitis in man which respond imperfectly to the therapeutic action of the serum are caused by meningococci resistant or "fast" to the antiserum employed. Also, under special circumstances the meningococci seem to acquire a serum fastness which thwarts the specific action; but the original fast strain is uncommon, and acquired fastness, at most, of only occasional occurrence. Although at first regarded as doubtful, it now appears that full-blown cases of meningitis are not wholly without the sphere of beneficial influence of the serum. The return of the practice of lumbar puncture as an aid to the diagnosis is serving to reveal the important fact that the influenza bacillus is a not infrequent cause of severe and usually fatal seropurulent cerebrospinal meningitis. Antiinfluenzal serum is just now being issued for use in man. It has been applied too seldom to warrant any deduction but one, namely, that under its influence the bacilli in the cerebrospinal liquid diminish in number and are taken up more freely by phagocytes. Other matters treated of are pneumococcus meningitis, tabes, and paresis.

**Hollow Foot—Pes cavus,** C. A. Parker states that so called true or essential cavus is rare. Cavus is practically always of neurogenic origin. Leaving out of account the paralytic calcaneus and possibly the congenital types, it is safe to assume that a perversion of the normal reciprocal action between the flexors and extensors of the toes can account for most, if not all, of the remaining types. In the initial stages simple measures commonly suffice to restore the normal balance, while in the fixed deformity severe force, often accompanied by resection of bones and section of soft tissues, is frequently required.

**November 22, 1912.**

**Indications from the Urine in the Treatment of Certain Diseases of the Skin,** L. D. Bulkley urges that, the urine being the most perfect exponent of the catabolism and anabolism of the system, too much stress cannot be laid upon the importance of its repeated and complete volumetric analysis in connection with the treatment of very many cases of diseases of the skin. He refers particularly to such dermatoses as eczema, psoriasis, acne, lichen planus, urticaria, and certain bullous dermatoses, and describes the urinary conditions under the heads of quantity, specific gravity, volumetric acidity, urea, indican, sulphates, chlorides, phosphates, urates and uric acid, and oxalates.

**Comminated Fracture of the Larynx; Accidental Tracheotomy; Multiple Trauma; Extensive Frostbite: Recovery,** D. B. Delavan records this case, which is that of a patient, now dead, who was formerly a well known figure in the
throat clinics of Central Europe, and who came to
this country about twenty years ago for the purpose
of making a living principally by the exhibition of
his throat at various medical schools. He was a
Roumanian, and received his injuries at the hands
of a band of outlaws, who hanged him to the limb
of a tree and left him to die. He struggled so
desperately that he not only caused a multiple fracture
of his larynx, but succeeded in breaking the rope.
His loudly stertorous breathing, however, quickly
attracted the attention of the bandits, who were still
in the vicinity, and he received three vicious cuts
with a large knife—one in the abdomen, one across
the face and over the forehead, and one straight
across the throat, passing between the thyroid and
cricoid cartilages and dividing the cricothyroid
membrane. He lay exposed to a temperature below
zero until the next morning, when he was discovered
and removed to a hospital. His ears, hands, and
feet were frostbitten, and so severe was his condi-
tion that he was obliged to undergo a Symes am-
putation of the right foot, a partial amputation of
the left foot, and the loss of most of the fingers of
both hands. Notwithstanding all these injuries, the
man recovered.

The Fundamental Principles of Biochemistry;
Their Application in the Study of Colloidal
Minerals, and Their Resulting Use in Medicine.
—J. A. Handy, in this paper, says: The reason why
most of the so-called organic salts of silver, mercury,
iron, etc., are not much more efficient or much less
poisonous than their purely inorganic salts appears
to be, the fact that most of them are merely loose
associations of the inorganic, poisonous, metal with
organic substances like albumin, casein, sugar, etc.
In order to become truly organic, or vitochemical,
the mineral part of the combination must be colloidal
in nature. All our wholesome, natural food is of
this character. Milk, butter, cheese, eggs, meats,
vegetables, fruits, etc., are colloids—not only their
protein, carbohydrate, and fat constituents, but also
their mineral bodies. These mineral bodies in true
organic or vitochemical form, which have been al-
most totally ignored in medicine and dietetics, ap-
ppear to be of such vital importance that not one of
the vital processes of the human organism is possi-
bile without them. Progressive physicians are
beginning to recognize that the mineral salts of our
food, which have been considered secondary in im-
portance to the proteins, carbohydrates, and fats,
are really of the first importance. The natural
mineral salts are not only of the first importance
as tissue foods, but are also the chief waste elimi-
nators in human metabolism. Is it not true that if the
physician can control nutrition he can control dis-
ease? If this is true, and the author believes it is,
then a thorough knowledge of the mineral salts in
true organic or vitochemical form—both in their
native occurrence in our natural foods and in their
synthetic forms—is necessary.

A New Method of Repair for Vaginal Hernia;
With a Report of 140 Cases in Which It Was
Used.—H. A. Wade describes this operation, a
special procedure in which is the dissecting upward
of a flap of mucous membrane, which is held clear
of the field of operation by means of a clamp, and
subsequently acts as an umbrella to protect the
plastic work done below from the irritating dis-
charges above. The distinguishing features of the
operation are mentioned as follows: 1. Fascia re-
pair; we have a fascia, and not a skin perineum
subsequently. 2. The mucous membrane flap pro-
tects the sutured tissues from irritating discharges,
and the operation may be done in the presence of
active bleeding from the uterus after an incomplete
abortion, and within four days after delivery in a
full term pregnancy. 3. The catgut is entirely
buried by sealing the wound with Michelin clips.
No catgut perineum can be a success if any catgut
is allowed to be exposed after the operation. 4.
The operation is a simple one and may be completed
in from six to ten minutes.

NEW YORK STATE JOURNAL OF MEDICINE.
October, 1913.

Near Death from Intravenous Injection
of Salvarsan.—Victor C. Pedersen's patient was a man,
fifty years of age, whose only ailments other than
his syphilis were a very slight grade of nephritis
and chronic alcoholism, of the type which results
from the long use of moderate quantities of the
drug. Within a few hours after the injection of
0.6 gramme, the patient went into a state of col-
lapse with pallor, barely palpable pulse, and pro-
fuse sweating. Although the man was in extremis,
he remained perfectly conscious. Immediate dra-
sic stimulation was instituted and within twelve
hours the patient had recovered. Following the re-
covery the urine was greatly diminished, contained
an abundance of albumin and was loaded with all
varieties of casts. It is believed that the cause of
the bad reaction to the salvarsan in this case was
to be found in the presence of an obscure alcoholic
myocarditis.

Infant Feeding with Undiluted Cow's Milk.—
William B. Hanbidge here adds the report of a
series of fifty patients fed on this plan, to his previ-
ously reported series of thirty-nine cases. Of fif-
ten cases in his own practice, five were suffering
from digestive disturbance while the others were
healthy. The whole milk disagreed with one of
the ten healthy children, but a mixture of whole
milk with cream overcame this trouble. All five of
the others, having digestive disturbances, did well on
the whole milk. The remaining patients in the
series were treated by other physicians and the re-
ports are equally favorable. Hanbidge calls atten-
tion to the fact that when the usual formulas are
given, the child is compelled to take an excessive
amount of fluid in order to get sufficient nourish-
ment. This, he believes, is a potent cause of inter-
digestive disorders. The use of whole milk over-
comes this tendency to overdilution of the stom-
ach, and permits of its proper emptying between
feeds, which is an essential factor in good digestion.
He finds that the use of from one and one half to
tw o and one quarter ounces of whole milk for each
pound of an infant's weight provides enough nutri-
ment for each twenty-four hours. The intervals
between feedings should never be less than two
and one half hours, better longer. The child, if
healthy, should be fed when hungry, rather than
by the clock, and should never be wakened to be
fed.
The Implantation of Fat in Tenon's Capsule.—Charles Nelson Spratt urges the implantation of fat after the enucleation of an eye, to form a mobile stump for the support of a prosthesis, as an operation that deserves a wider use. He asserts that by the use of fat a sterile, autogenous graft is secured which, when inserted within Tenon's capsule, has less tendency to change its position than any foreign substance. It offers little or no chance for extrusion, unless an infection takes place, or faulty methods of suturing are used. The conjunctiva is divided close to the limbus and dissected backward beyond the insertion of the recti muscles. These are picked up on a strabismus hook, separated from the surrounding tissue, each is caught by a small, delicate hemostat, their tendons cut at their insertions, and the eye enucleated in the usual manner. A piece of subcutaneous fat is then removed from the abdomen, inserted in the cavity left by the eyeball, the superior rectus is sutured to the inferior by a mattress suture of double O chromaticized catgut, the loop placed beneath the inferior and the knot on the outer surface of the superior. The two lateral recti are sutured in a similar manner, each needle being passed through the previously sutured recti. By this method a fixed point for all four muscles is formed. The conjunctiva is closed by a purse-string suture.

The Care of School Children at Moorfields.—Samuel Horton Brown discusses the difficulties met with in the eye clinics in the larger cities of the United States when they find themselves overwhelmed by thousands of refraction cases referred to them by the school inspectors. Unfortunately they all appear well nigh simultaneously, and consume the most of the time of the junior assistants. He then describes what he found in the Royal London Ophthalmic Hospital, which is a very large institution. Being essentially a graduate school the assistants and students are averse to this dry, monotonous work, preferring to see inflammatory and surgical cases. Yet it is fitting that the children should be examined and prescribed for in a well-equipped hospital with skilled consultants at hand, rather than in a poorly equipped department of some municipal bureau. The London County Council agreed to pay the hospital £1,000 annually to care for not more than 5,000 children who require glasses. The hospital retains one half of the money received to cover its expenses, and divides the balance equally among the five physicians who are in attendance. The hospital equipped a model department, separate from the other clinics, which is practically a school eye clinic. Five physicians are engaged, together with part of the time of the nursing, domestic, clerical, dispensing, and optical staff. It is so arranged that each doctor sees not more than twelve new cases daily, and such old cases as have been returned to his service. Nothing but refraction cases are attended to. An optician attends daily and is authorized to charge certain prices for the glasses. If these prices cannot be paid an arrangement is made by which they can be obtained free. These glasses come in for criticism. "Rimmed glasses are the proper style and the saddle bridge is fitted without regard to centering or anything else, that is, as we understand such things. The diameter of the lenses bears no relation to the size of the eye, or to the interpupillary distance, but the sizes are selected solely by inspiration." Gold or gold filled frames are considered an extravagance. The efficiency of the inquiry officer as a means of eliminating the dispensary dead beat and increasing the hospital's revenues at the same time is dwelt upon at some length.

Burn of Eyeball Due to Caustic Contents of Golf Ball.—L. W. Crigler relates the case of a boy whose eye was severely burned by the contents of the small rubber bag in the centre of a golf ball which he was cutting up.

Proceedings of Societies.

CLINICAL CONGRESS OF SURGEONS OF NORTH AMERICA.

George Emerson Brewer, M.D., President.

(Continued from page 1090.)

Educational Value of Cancer Statistics to Insurance Companies, the Public, and the Medical Profession.—Mr. Frederick L. Hoffman, of Newark, New Jersey, stated that during the year 1910 the average age at death in cancer and other malignant tumors combined was 59.2 years for the registration area of the United States. For males the average age at death was 60.4 years, and for females, 58.4 years. Considered by organs or parts affected, the average age at death in cancer of the buccal cavity was 63.1 years; in cancer of the stomach and liver, 61.2 years; in cancer of the female generative organs, 53.8 years; in cancer of the breast, 58.3 years; in cancer of the skin, 68 years; and in cancer of other organs and parts not specified, 56.9 years. Cancer was distinctly a disease of advanced adult life. Of the mortality from all causes in the registration area, ages forty-five and over, the proportion of deaths from cancer was 8.6 per cent., or, respectively, 6.4 per cent. for males and 11.2 per cent. for females. During the decade ending with 1911 the cancer death rate for all ages had increased from 63.8 per 100,000 of population in 1901 to 83.9 in 1911. The cancer death rate of males had increased from 48.7 per cent. to 64.2 per 100,000 of population, or 31.8 per cent; and the cancer death rate of females had increased from 83 to 104, or 25.3 per cent. Considered by divisional periods of life, the death rates had increased at all ages and for both sexes, with unimportant exceptions, at ages from five to fourteen inclusive. For males the increase in cancer during the ten year period, and at the ages from forty-five to fifty-four, was twenty-one per cent.; at ages from fifty-five to sixty-four, it was thirty-nine per cent.; at ages from sixty-five to seventy-four, it was forty per cent., and at ages seventy-five and over, it was also forty per cent. For females the increase in the cancer death rate at ages from forty-five to fifty-four was...
eleven per cent.; at ages from fifty-five to sixty-four, it was twenty-seven per cent.; at ages from sixty-five to seventy-four, it was thirty-two per cent.; and at ages of seventy-five and over, it was forty-four per cent. There was sufficient evidence to sustain the conclusion that in quite a number of cases suicide the underlying motive for self murder was the insufferable torture of a hopeless case of cancer, and while here again the statistical evidence was incomplete and not available for the country at large, there were a sufficient number of individual cases on record to warrant the conclusion that the recorded cancer death rate was perceptibly diminished on this account.

Cancer, in the experience of life insurance companies, has been the subject of occasional consideration, but not of very extended and thoroughly specialized inquiry. A review of the available statistics, extending over more than a century, tended to confirm the conclusion that, during the long intervening period of time, the mortality from cancer had gradually and persistently increased, from a comparatively low rate of frequency to proportions which might appropriately be considered a menace to civilization. The earliest data are those of the London Equitable Society, for the period 1800-1821, in which, out of 1,630 deaths from all causes, only twenty-five, or 1.5 per cent., were from cancer; or, eliminating deaths under age of forty, it appeared that out of 1,720 deaths from all causes, twenty-four, or 1.4 per cent., were ascribed to cancer.

A large number of physicians had been reached in an effort to improve medical education with reference to the earliest possible diagnosis of the disease. Since in Germany a large number of confinements were without proper medical attendance, but under the supervision of more or less qualified midwives, a special effort was made to reach this class, also with fairly satisfactory results. Finally, the public at large was reached through articles prepared by laymen for publication in the principal newspapers and periodicals. A special leaflet was prepared for public distribution on a large scale, which contained in the simplest form the required but pertinent suggestions to women, and especially that class approaching the change of life. One of the chief objects of the campaign had been to warn the public against blind faith in alleged cancer cures, and treatment by unqualified physicians or quacks. Winter was able, in 1911, to report that out of 1,000 cases of cancer of the uterus in his experience, twelve per cent. of the women had come to him during the first month of the probable beginning of the cancerous growth; in thirty per cent. of the cases, the duration had been over one month; in twenty-seven per cent. over three months; and in forty per cent. over six months. One of the most recent contributions to the subject was a study of the statistics of cancer of the breast, by Dr. Ernst Schwarzkopf, of the surgical clinical of Prague, who found that out of 350 cases of cancer of the breast, 321 were operable and only thirty-nine were not operable. Practically all of the early cases which came to him, say of less than six months' duration, were within the operative group. He included a table giving the operative mortality among early surgeons, and those of more recent times, which showed a most gratifying reduction in the mortality rate. The investigation suggested a corresponding collective study of the subject for this country, which probably more than anything else would aid the efforts of the Society for the Control of Cancer to bring about a nation wide interest in the facts, and by degrees, a reduction in the mortality rate from this always lamentable disease. For the present purpose the speaker had made a special analysis of the General Memorial Hospital of New York with the following results: This hospital, during the period 1902-11, treated 1,337 patients on account of malignant disease. Of this number, 531 were males and 806 females. Of the total number treated, 460 or 34.4 per cent. were cured; the number of improved was 301 or 23.2 per cent.; the number of not improved cases was 266 of 19.9 per cent.; and 11.5 or 8.6 per cent., were either not treated or remained in the hospital at the end of the period. There were 195 deaths, equivalent to a fatality rate of 7.9 per cent.

There were the strongest possible reasons for believing, however, that if the cancer facts, including medical and surgical experience, were brought together in an authoritative form, they would not only materially aid the work of the American Society for the Control of Cancer, but the various cancer research funds, as well as the individual practitioner in his relations to the patients and the public at large. With this end in view, however, it was necessary that there should be intelligent and active cooperation between the laity and the profession, on the one hand, and the life insurance companies and the Federal and State governments, on the other.

A Very Recent Investigation of the Outcome of the Cases of Cancer Recorded in the Johns Hopkins Hospital and the Surgical Pathological Laboratory.—Dr. Joseph C. Bloodgood, of Baltimore, said that in eighty-five cases of benign lesions of the lip there were one hundred per cent. of cures. In lesions of the lip which to the sight and touch seemed benign, but which under the microscope proved to be early cancer, there were nine cures, ninety per cent. The failure to cure in the one case was due to an incomplete operation on the lower lip. When the lower lip only was removed and not the glands, they had cured but seven patients, or sixty-three per cent. The failure to cure in four cases was due to the involvement of the glands under the jaw. When the complete operation was performed, that is, removing the lesions of the lip and the glands of the neck, there had been twenty cured five years, or ninety-five per cent. If the lesion of the lip had had previous treatment and had recurred on the lip, and the recurrence was cancer, the probability of a cure was reduced from sixty-three to twenty per cent., ninety-five to sixty per cent., and fifty to twenty per cent. The operation for recurrent cancer of the lip reduced the probability of a cure at least forty-two per cent. Similar figures could be duplicated with lesions of the tongue, face, skin of the body, and extremities.
The same investigation was now complete with over one hundred lesions of the skin and mucous membranes.

As to cancer of the breast, in the least malignant forms, there were thirty-five patients cured, five years or more after operation. There were fifteen patients who came for treatment so early in the disease that a diagnosis of cancer could not be made out until at the operation when the lump was explored. Every one of these patients had remained well five years or more, that is, one hundred per cent. of cures had been accomplished when the operation had been in the early stage in the less malignant forms of cancer of the breast. In this same form of cancer there had been twenty patients who came for treatment late. The same complete operation was performed, but the percentage of cures was but sixty-four per cent.

Results, therefore, in the less malignant form of cancer of the breast were: thirty-five cases, seventy-six per cent. of cures; early cases fifteen, one hundred per cent. of cures; in twenty late cases, sixty-four per cent. of cures. The figures thirty-five, fifteen, and twenty represented the actual number of cured patients. The per cent. of cures in all cases of cancer in which complete operation could be done, and in which the period of time since operation was five years, was now forty-two per cent. Five years ago it was only thirty-five per cent.

In cancer control and precancerous lesions the great hope for increasing the number of cures of cancer and decreasing the number of deaths from cancer lay in the education of the public and the profession on the significance and potential danger of the precancerous lesion, the education of the surgeon as to the best surgery, and the education of the surgeon and the pathologist as to the recognition of the earliest stage or the beginning of cancer in the benign precancerous lesion. Incomplete treatment in the earlier stage of cancer often yielded a worse result than complete treatment in a later stage.

Further Observations on Chronic Intestinal Stasis.—Sir Arrathnot Lane, of London, mentioned a case that taught him how a patient might lead an active and happy life with only a small portion of the jejunum left after operation. In this case he removed a large portion of the jejunum, after which the patient gained in weight rapidly and her strength improved correspondingly. The knowledge he gained from operating in this and similar cases had been of the greatest importance to him and had enabled him to save a number of lives. He referred to the circumstances which led him to remove the large bowel for chronic intestinal stasis.

Chronic intestinal stasis was one of the most formidable causes of crime. Several patients had attempted suicide on account of chronic intestinal stasis, and in all such cases the removal of the large bowel had restored the sufferer, not only physically but mentally. The headache of varying intensity from which these unfortunate suffered was also relieved by the operation, also the sleeplessness which accompanied it. Such patients put on fat, the pallor and staining of the skin disappeared and were replaced by a healthy color. He quoted Dr. James Mackenzie as saying that the majority of degenerative changes in the heart were due to autointoxication. Doctor Mackenzie sent him a patient from whom he removed the large bowel with the greatest benefit to the cardiac condition, as well as to the general well being of the patient. To summarize: Of 106 cases in which he had performed the short curitizing operation for chronic intestinal stasis there had been four deaths.

On the Relation of the Ductless Glands to the Work of the Surgeon.—Dr. Roswell Park, of Buffalo, New York, said that the internal secretions, so often spoken of as hormones, exercised an apparently controlling influence on many of the organs and functions, and this not alone on the ordinary body functions, but on the nutrition and regulation of individual organs and their particular activities, even to the extent of becoming responsible for the development of certain mental traits or personal characteristics which might make or mar the individual, and might thus affect both his physical and intellectual welfare. For example, dwarfin and gigantism, each of which seemed due to the under- or over-erted activity of one or more of the ductless glands, naturally affected the social and school life of the growing child, and to such an extent that when conspicuous deformity resulted the entire course of life was affected to an extent which might be appalling. The hypophysis, as a whole, was a persistent organ and, therefore, must have throughout life a continued function. Extracts of the whole gland increased pressure, caused uterine contraction, increased peristalsis, lowered carbohydrate assimilation, and had a mydriatic effect. Used to excess they caused emaciation, degeneration of the liver, and increased metabolism. Extirpation produced in animals a peculiar cachexia, reduced pulse rate and respiration, and caused fibrillary tremors and death from apathy and coma. The overgrowth of the pituitary sometimes occurring after typhoid fever, or its clinical evidences, was to be considered as the result of toxines which stimulated its growth, as well as perhaps that of the epiphyseal bony borders, thus accounting for excessive overgrowth after this fever. Something of the same kind was often seen after marriage when the stimulation of the sexual glands seemed to extend in a short time to the hypophysis. As to the influence of the ductless glands in general on growth and development, it was found that a loss of the genital glands in youth led to overgrowth of the truncal skeleton, while the cranium did not seem to grow so fast. The distribution of fat about the body was disturbed. Epiphyseal consolidation in those places where it naturally occurred least or last was delayed. This would account for the overgrowth, and it was not necessary to seek for its cause in the pituitary. The sexual glands, therefore, especially at puberty, exerted a marked influence over the development of the bones during the last portion of adolescence.

Even to-day there was much to learn concerning the functions of the thyroid. It was once regarded as a reservoir by means of which blood pressure in the brain was equalized. It seemed to have an influence on the formation of the blood, slightly resembling the action of the spleen, possibly acting
vicariously for it. The most important part of its work appeared to be elaboration of iodothyrine. Certainly iodine was its most important constituent, and in this the thyroid was richer than any other organ.

The parathyroids, these four little bodies, had only within late years been given their proper consideration, and in that short time had attained an importance in pathology quite disproportionate and in inverse ratio to their size. It was now generally believed that nearly all causes of tetany in man were of thyroidal origin, and due to defective nutrition and consequent evidences of hypoparathyroidism.

Conditions which required surgical intervention were the thyroid extirpation, which must be partial, save when dealing with malignant disease, ligation of bloodvessels, transplantation as in tracheotomy, operations for consequences of osteomalacia, achenodroplasia, etc., involving the pelvis as Cesarean section, etc., operations on the teeth and jaws for various congenital defects, cleft palate, etc.

A Summing Up of the Goitre Question.—Dr. Charles H. Mayo, of Rochester, Minnesota, stated that various enlargements of the thyroid were the result of temporary excessive physiological demands, as at puberty, pregnancy, infection, menstruation, etc. Many goitres of the simple and mild exophthalmic type undoubtedly recovered spontaneously and, in many instances, various forms of medical treatment might hasten the recovery and restoration of the gland to an apparently normal condition. Simple goitres of long standing were often thrown into degeneration by giving iodine, causing thyrotoxicosis, but not exophthalmos, although some symptoms were the same in these two forms of toxic goitre. Encapsulated adenomas and simple colloid goitres which had resisted treatment were in most instances best treated by removal of enough of the gland to extirpate the disease. In simple goitre the more enlarged lobe should be extirpated; encapsulated adenomas should be enucleated and thyroids which were bilaterally enlarged should have double partial resections with division of the isthmus. Exophthalmic goitre was essentially a disease chronic in character, presenting exacerbations and ameliorations of symptoms extending through a period of months or several years. While this disease was amenable to surgical treatment by the removal of a large part of the hypersecreting gland, this procedure should by no means be considered emergency surgery, and during exacerbations all cases should be considered medical. Surgery was indicated during the upward wave of improvement. Extreme conditions, especially dilatation of the heart, might require preparation medically before instituting operative interference, and this should be confined to a preliminary ligation of the left upper pole. Should reaction follow this, ligation of the right upper pole was indicated a week later and thyroidectomy reserved until the patient had gained in weight and general health. Otherwise thyroidectomy was made at a second operation. In operating on the thyroid the best exposure was obtained by the curved transverse incision through skin and platysma between the anterior jugular veins, making a wide separation of the flaps, and a midline vertical division of the muscles to expose the thyroid. This division should be made high near the insertion to break the line of the scar and preserve the function of the muscle. In some cases the wound might be closed without drainage, the cavity being filled with salt solution. As a rule, however, patients were more comfortable if drainage was instituted for twenty-four hours. A subcuticular closure of the wound with catgut, approximating the platysma muscle, secured an almost imperceptible scar.

(To be concluded.)

Book Reviews.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

This translation of the fourth German edition of Quervain's work on surgical diagnosis will be welcomed by the English reading medical student and by any one considering the subject of surgical diagnosis from a standpoint not usually taken in books on this subject. In place of describing the surgical condition under discussion and enumerating the various affections which may be mistaken for it, it gives first the findings of a physical examination and then constructs a diagnosis on these findings. Later the student is taught to clinch the diagnosis by a process of exclusion of the various allied conditions. As this is the method actually used by the successful practitioner at the bedside, its value to the beginner cannot be too highly emphasized. Quervain shows himself a master in this form of diagnosis and his book should be an inspiration to teachers of surgery. Furthermore, the book contains a full and accurate description of the various aids to diagnosis with which no surgeon should be unfamiliar. These include bacteriological, histological, serological, and radiographic investigations. The author has put into the work the results of his own experience, not only in the clinic, but also in the classroom, and for this reason the book has a personal touch and a vividness of description not often found in textbooks. The illustrations, most of which are taken from personal cases, are unusually clear and well executed. They are of great value in helping the student to fix in his mind a picture of the various surgical affections. The book should have a wide distribution and is particularly adapted to the needs of third and fourth year students in our medical schools.

Gynecological Operations. Including Nonoperative Treatment and Minor Gynecology. By Henri Hartmann, Professor of the Faculty of Medicine, Paris, Surgeon to the Laennec Hospital, Paris, etc. Authorized Translation Under the Author's Supervision by Douglas W. Shirlow, M.B., Ch.B. Edin., Formerly Physician to the British Hospital, Levallois-Perret, Paris. With 422 Illustrations, a Number of Which are in Colors. Philadelphia: P. Blakiston's Son & Co., 1913. Pp. xvii-536. (Price, $7.)

In this work the author has endeavored to give as complete an exposition as possible, of the various methods of treatment employed in gynecology, and it is for the opinion of this experienced teacher and authority on disputed questions, in the treatment of diseases of women, that the reader will most probably search the pages of his book. Apart from the descriptive operative technic of Doctor Hartmann with conservatism as his guide, together with brief references to the procedures of other gynecologists, the author has very wisely given an important place to the nonoperative treatment of the subject, recognizing the fact that there is a general return to this branch of therapeutics.
Careful consideration is given to minor gynecology, electrotherapy, the mineral water cures, and kinesthesia. The book is based on the science of choice and to a large number of figures and diagrams to illustrate each stage of an operation, also the details of ante partum and post partum treatment.

The book is eminently practical, characteristic of the author's containing 438 illustrations, which will be of value to all who treat gynecological cases.

The sixth edition of Binnie's well known work on operative surgery marks a great improvement in our textbooks on this subject. The work represents a ripe experience of a practitioner in surgery which insures a practical treatment of operative methods. Furthermore, there is present in this work an unusually clear description both of the indication and objects of the operation, and of the various steps in technic. Every chapter is bristling with useful points which have been found helpful to the author after years of experience, and will be of infinite value to the student and practitioner first approaching any particular operation. The author has included many of the older methods of procedure which have long since ceased to be used in our modern technic and which are employed now only in the field of operative surgery in the cadaver. On the other hand he has included all the modern operations, many of which are performed chiefly by the specialist in that field. These rarer operations, such as, for example, the removal of the Gasserian ganglion, are described with great accuracy, so that they become perfectly intelligible to the student, as well as sufficient in detail to the surgeon who wishes to perfect himself in the technic of these operations. The book will be a great help to students and beginners in both their work, and to the general surgeon who wishes to familiarize himself with any new form of operative procedure.

*Diagnosis of the Malignant Tumors of the Abdominal Viscera.* By Professor RUDOLPH SCHMIDT, Professor of Medicine in the University of Innsbruck. Authorized English Version by JOSHD BURK, Sc.D., M.D., Atten. to the Buffalo Hospital of the Sisters of Charity, etc. New York: Reckman Company, 1913. Pp. xiii-361. (Price, $4.)

To either the surgeon or the internist this book should prove extremely useful. The first part takes up the general considerations concerned in making a diagnosis of an abdominal tumor. A term employed in making the physical and clinical examinations are given and some interesting points are mentioned in the suggestions for the taking of histories of malignant neoplasms. The remainder of the book is given over to differential diagnosis between tumors and conditions simulating them and to the presentation of case histories. Of cancer of the stomach 105 are given, the other organs not represented in such large number. The histories are interesting and instructive, and the book will be highly recommended to both the medical student and because the diagnostic part is so well presented.

Since the publication of the various acute abdominal lesions has become complete through the investigations of the pathologist, the internist, and the abdominal surgeon, a want has been felt for some book dealing solely and exhaustively with all the acute abdominal emergencies encountered at the bedside. The value of such a book both for the physician and surgical consultant is inestimable in that it brings together the various lesions and compares and contrasts them. The present volume is the first to undertake this function and the authors are to be congratulated on its clear and complete arrangement when they have done their work. Such a book could be written only by a practising surgeon who has familiarized himself also with the diseases of other localities simulating acute abdominal disease. In addition to the description of the pathologic anatomy and clinical symptoms, the authors have inserted an account of illustrative cases taken from their own experience. The work is of chief value to the physician and surgeon in actual contact with these acute abdominal emergencies. As the fate of the patient is primarily in the hands of his first medical adviser it is he who would profit most by the assimilation of the valuable information contained in a book dealing with these most important conditions.

*A Treatise on the Diseases of Women.* For Students and Practitioners. By PALMER FISKEL, B.S., M.D., Professor of Gynecology, Am. College of Medicine, State University of Nebraska; Gynecologist to the Clarkson Memorial Hospital and the Douglas County Hospital. Illustrated with 832 Engravings in the Text and Thirty-eight Plates in Colors and Monochrome. Philadelphia and New York: Blakiston's Son & Company, 1913. (Price: $4.)

Although this book is an outgrowth of the author's Diagnosis of Diseases of Women it is so extensively revised and enlarged that there is little resemblance. This present volume covers the subject very thoroughly and in an up to date manner. The illustrations are numerous and well done, and aid the student greatly in understanding the matter. In every way this textbook forms a valuable addition to the literature.

During the four years since the first edition of this work was published, the progress in vaccine and serum therapy has been such as to warrant a large number of changes in the present edition. The new methods including the principles of specific diagnosis of the causative factor has been added: this being supplemented, in the last chapter, with the differential diagnostic points "for infection with each of the organisms for which specific therapy is desirable. Seralum, the term is treated in a separate chapter with immunity; specific diagnosis; specific therapy; specific chemotherapy; specific diagnosis, treatment, and prophylaxis in the different infections; and diagnosis, treatment, and prophylaxis in syphilis and malaria, as an appendix. The work, though essentially a textbook of differential diagnosis, is printed and reflects credit upon both author and publisher.

*Interclinical Notes.*

Physicians will be interested in Through the Land of Witchcraft, by P. Amaury Talbot, the fourth installment of which appears in the December *Wide World Magazine.* Many instances are given of the treatment of disease by witchcraft, while fetish stones, the river that brings good luck, secret societies, and sacred musical instruments are other subjects of entertaining and significant description.

Physicians, being often chosen to act on town schoolboards, will read with interest and attention the essay of Charles Leonard Moore on Education in the *Dial* for November 16, 1913. The dangers of vocational training, which seems so ideal to the unthinking taxpayer, are clearly indicated in the inevitable references made relative to Greek and Latin methods are so little known to the students of the present generation. Are doctors apt to be materialists, as Mr. Moore avers? Mr. Moore attributes the materialism to the lack of thorough preliminary education, and says that we have found out that the slight taste of many kinds of knowledge, which is what we have endeavored to give American youth during the past hundred years, is the worst possible preparation for the struggle of life. We commend this essay to our friends, for it runs counter to many principles tacitly accepted by our imperfectly equipped schoolboards.
Meetings of Local Medical Societies.

MONDAY, December 8th.—Society of Medical Jurisprudence, New York; New York Ophthalmological Society; Williamsburg Medical Society, Brooklyn; New Rochelle Medical Society; Corning Medical Association; Watervliet, Conn., Medical Association.

TUESDAY, December 9th.—New York Academy of Medicine (Section in Neurology and Psychiatry); New York Obstetrical Society; Medical Society of the County of Schenectady; Medical Society of the County of Rensselaer; Buffalo Academy of Medicine; Jamestown Medical Society; Rome Medical Society; Practitioners’ Club of Jersey City, N. J.

WEDNESDAY, December 10th.—New York Pathological Society; New York Surgical Society; Medical Society of the Borough of the Bronx; Alumni Association of the City Hospital (annual); Brooklyn Medical and Pharmaceutical Association; Alumni Association of the Norwegian Hospital, Brooklyn; Medical Society of the County of Richmond, N. Y.; Dunkirk and Fredonia Medical Society (annual).

THURSDAY, December 11th.—New York Academy of Medicine (Section in Pediatrics); West Side Clinical Society, New York; Brooklyn Pathological Society; Blackwell Medical Society of Rochester, N. Y.; Jenkins Medical Association of New York, N. Y.; Buffalo Ophthalmological Society; Jamestown Medical Society; Society of Physicians of the Village of Canandaigua; Gloversville and Johnstown Medical and Surgical Association; Physicians’ Club of Middleboro.

Friday.—New England Academy of Medicine (Section in Otolaryngology); New York Society of Dermatology and Genito-urinary Surgery; Eastern Medical Society of the City of New York; Society of Clinical Serology, New York; Society of Alumni of St. Luke’s Hospital; Society of Ex-Interns of the German Hospital in Brooklyn; Saratoga Springs Medical Society.

SATURDAY, December 12th.—Therapeutic Club, New York.

Official News.

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending November 29, 1913.

Gwyn, M. K., Surgeon. Granted thirty days’ leave of absence from December 18, 1913. Kearny, R. A., Assistant Surgeon. Directed to proceed to New York, N. Y., for the purpose of making preliminary arrangements and preparations relative to an exhibit by the Service at the International Exposition of Safety and Sanitation which is to be held in New York, December 11 to 19, 1913.

Lumsden, L. L., Surgeon. Detailed to represent the Service at the annual conference of county health officers, called by the State Board of Health, to meet in Louisville, Ky., December 8 to 10, 1913.

Phelps, E. B., Professor. Directed to proceed to Wilmington, via Raleigh, N. C., upon request of the State Board of Health, for the purpose of investigating the local water supply and making recommendations in respect thereto.

Voegtlin, Carl, Professor. Directed to proceed to Savannah, Ga., for conference with the officers engaged in pellagra investigations.

Board of Medical officers directed to proceed to the purpose of preparing questions for the mental examination of several assistant surgeons engaged in the department of mental hygiene. The officers are appointed assistant surgeon in the Public Health Service, who will report at the Marine Hospital, St. Louis, Mo., December 1, 1913. Detail for the board: Assistant Surgeon General W. G. Simpson, chairman; Assistant Surgeon General W. C. Rucker, member; Assistant Surgeon R. A. Kearny, recorder.

Board of medical officers convened to meet at the Marine Hospital, St. Louis, Mo., to conduct the medical and physical examination of a candidate for appointment as assistant surgeon in the Public Health Service. Detail for the board: Surgeon Mark J. White, chairman; Acting Assistant Surgeon H. C. Wakefield, recorder.

Advisory board of the hygienic laboratory convened to meet at the bureau, Saturday, December 13, 1913. Standing board for receipt of alien immigrants at Honolulu, Hawaii, convened as follows: Surgeon F. E. Trotter, chairman; Passed Assistant Surgeon E. R. Marshall, member; Passed Assistant Surgeon C. M. Fauntleroy, recorder.

United States Army Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Army for the week ending November 29, 1913.

Eckels, Laurens S., First Lieutenant, Medical Corps. Will report in person on December 2, 1913, to Lieutenant Colonel Henry C. Fisher, Medical Corps, president of examining board at the Army Medical Museum Building, Washington, D. C., appointed in paragraph to Special Orders No. 2 G., War Department, for examination to determine his fitness for promotion; on completion to return to proper station. Lieutenant Eckels is relieved from duty at Fort McKinley, M., to take effect at such time as will enable him to comply with this order, and will proceed at the proper time to Fort Du Pont, Del., and report in person or on or about December 15, 1913, to the commanding officer of that post for assignment to duty to accompany the Eighty-first Company, Corps of Army Medical Corps, to Cristobal, C., and will proceed with the organization named to Fort Grant, C. Z., for station.

Gilchrist, H. L., Major, Medical Corps. Will proceed to Asheville, Raleigh, and Kinston, N. C., on December 9, 11, and 12, 1913, respectively, for the purpose of making a special inspection of Ambulance Co. No. 1, Field Hospital, and Hospital Corps Detachment, Organized Militia of North Carolina, and upon the completion of this duty will return to his proper station.

Murtagh, John A., Major, Medical Corps. Granted leave of absence for three months on surgeon's certificate of disability; on expiration of this leave will proceed to Letterman General Hospital, Presidio of San Francisco, Cal., for observation and treatment.

Married.

Dundon—Gray. In Plainfield, N. J., on Saturday, November 15th, Dr. Arthur Hall Dundon and Miss Frieda Theodora Gray.

Died.

Ayres.—In Fort Plain, N. Y., on Thursday, November 26th, Dr. Douglas Ayres, aged seventy-one years.

Bashore.—In West Fairview, Pa., on Wednesday, November 19th, Dr. Daniel W. Bashore, aged seventy-eight years.

Bell.—In Penosha, Wis., on Thursday, November 20th, Dr. William Roscoe Bell, of Marinette, Wis., aged sixty years.

Brainerd.—In Plainfield, N. J., on Tuesday, November 18th, Dr. Lucien La Brand Brainerd, aged sixty years. Edwards.—In Richmond, Va., on Wednesday, November 12th, Dr. Robert Lide Edwards.

Gaston.—In Montgomery, Ala., on Saturday, November 15th, Dr. John Overman Gaston.

Goodwin.—In Minneapolis, Minn., on Saturday, November 15th, Dr. Russell F. Goodwin, aged seventy-two years.

Helbig.—In New York, on Wednesday, November 19th, Mrs. Freda Helbig, aged forty-six years.

Hendricks.—In Philadelphia, Pa., on Wednesday, November 19th, Dr. Albert W. Hendricks, aged seventy-three years.

Hobson.—In Hampton, Ia., on Saturday, November 15th, Dr. Carl Lyle Hobson, aged seventy-eight years.

Jenkins.—In San Francisco, Cal., on Thursday, November 16th, Dr. Ira D. Isham, Jenkins.

In Kilbourn, Wis., on Thursday, November 15th, Dr. George W. Jenkins, aged ninety years.

Morrison.—In Richmond, Cal., on Sunday, November 15th, Dr. M. Morrison, aged eighty-seven years. Neptune.—29th, Ind., on Sunday, November 23rd, Dr. Harry M. Winans.
Original Communications.

PUS IN THE URINE.*

BY VICTOR COX PEDERSEN, A. M., M. D.,
New York.

Pus in the urine or pyuria may be defined briefly as pus associated with the act of urination in quantities sufficient to discolor the urine or be a factor on microscopical examination. It may therefore be regarded as a symptom, but it is one of such grave importance and of such severe possibilities for the patient, that its source and cause must be searched for and settled without delay. In general its significance is regularly an inflammatory process of severe character resulting in pus formation after the usual pathological manner which needs no elucidation here.

Like hematuria pus may originate from any of the ordinary subdivisions of the urinary and genital tracts; for example, in the male from the foreskin, the anterior urethra, the posterior urethra, and the periurethral structures—notably the prostate; and in the female from the vulva, the vagina, the uterus, and the urethra corresponding with the posterior urethra in man; and in both sexes from the bladder, either or both ureters, ureteral pelvis and kidneys. It therefore becomes the duty of every practitioner to know as far, and as early as possible, every detail of pus in the urine which has reached any important and persistent amount. The dictum that pyuria may mean pus as a factor in microscopical examination means, obviously, much more than the scattered cells invariably seen in urine.

If we classify pyuria from the standpoint of its anatomical sources as just described, we shall have in the male balanic, anterior urethral, posterior urethral, periurethral; and in the female vulvar, vaginal, uterine, urethral; and in both sexes vesical, unilateral and bilateral ureteral, ureteropelvic and renal. The activity of the pus production determines acute, subacute, and chronic forms, scanty, moderate, or copious in amount, intermittent or remittent, and recurrent or persistent in course.

The essential cause is infection and the special organisms of the infection are so well known that they may here be omitted. Your president has asked for practical observations, and therefore without further discussion of the various didactic elements of pyuria, let us proceed to give one case in the male illustrating each of the important forms.

*Read by invitation before the Lake Keuka Medical and Surgical Association, Lake Keuka, N. Y., July 17 and 18, 1913, and before the Yorkville Medical Society, New York, October 20, 1912.

Balanic pyuria may be very copious, highly irritating and painful, and deceive the unwary and casual observer into the diagnosis of acute gonococcal urethritis. From this condition in addition to the bacteriological findings it should be quite readily recognized by the fact that on close questioning there is no urethral ardor, tenderness, nor other signs of inflammation. Retraction of the foreskin instantly locates the disease and reveals its character as simple, chancroidal, or chancrous in middle life, and in age neoplastic, and the inflammatory as adhesive. When retraction cannot be performed attempt at dilatation of the mouth of the foreskin with a three blade nasal speculum and illumination of its cavity with a urethrosopic lamp should be tried. Palpation becomes an important factor, as any lesion such as new growth in its broadest sense, used to include the ulcerations and the neoplasms, may readily be outlined and its character suggested if not determined. The character of the pus to the naked eye is important in its variations from mucoid in simple, serous in syphilitic, and bloody in chancroidal and neoplastic cases.

In the total perhaps the most important cases for us in the male are those of syphilitic balanic pyuria which, as in all other cases, shows only a little pus in the first glass of urine, even in a small specimen. The following is a case in point referred to me by Dr. J. Milton Mabbott, New York.

Case I. C. J.; Ireland; white; twenty-eight years old; single; houseman (case 12567); first seen December 21, 1911; diagnosis, acquired syphilis in second stage. Former venereal history: Admitted having had gonorrhea once, two years ago, without complications. He was treated by a physician, for one visit, with internal measures. No sign of urethral damage in the urinary test glasses. This was undoubtedly not a gonococcal infection, but was probably only a balanitis whose pus deceived a careless examiner. Open lesions denied. The present venereal history stated that his sexual habit was weekly intercourse with any woman, infection acquired about seven weeks and symptoms about six weeks previous to his first visit. The very slight amount of pus, its serous character, the benign symptoms, all were counter to the diagnosis of gonorrhea which the man at first insisted that he had. The foreskin could not be retracted, contrary to his usual experience. Palpation revealed a hard spot which, on questioning, he said corresponded with a simple looking chafe, noted about three weeks after connection, which by extension had produced the phimosis. The diagnosis was clear: Syphilitic chancere, balanoposthitis and phimosis. A secondary rash and a .44-.4. Wassermann reaction settled the matter and made the institution of proper treatment prompt and unwavering.

Urethral pyuria in the male is our next topic. We pass gonococcal urethritis by as so specific as to be hardly germane to our subject, excepting that the germ must always be looked for in smear and
culture. For the distinction of the point of the urethra from which the pus proceeds no test is better in the writer's opinion than the Wolbarest five glass test. This test is not without some danger of infecting the bladder which the writer meets by giving the patient urinary antiseptics before and after it for a few days and, at the time, washing out the bladder.

An example of what careful diagnosis in urethral pyuria may lead to is shown by the following case reported in a previous contribution.²

**Case II. H.; United States; white; thirty years old; married; draughtsman. Diagnosis, initial anteroposterior urethritis. (Case XIII); referred by Dr. T. K. Tuthill. Former venereal history denied. Acquired present infection five years ago, after six or seven days incubation. Had never been free from discharge. Wife apparently not infected. Numerous relapses, independently of any exposure, had occurred. Diurnal urination every three hours; nocturnal twice. Urethral, tenesmus, and chordee moderate; control fair. Both glasses of urine were rich in pus. Uralanalysis negative; culture of pus negative for gonococci, but showed a large Gram positive diplococcus, both intracellular and extracellular. Gonococci not found by culture or smears. The local treatment of this case was along modern lines with ascending hand injections of zinc sulphate. The particular features of the pus, however, impressed me with the feeling that the patient had overdone the treatment. I, therefore, submitted him to a careful urethroscopy, and found the urethra, from end to end, to be practically covered with a scarred, puckered appearance, as though there was largely a meatal urethritis present. Moreover, a number of prostatic ducts were patulous and seemingly infected; the verumontanum was covered with unhealthy granulation tissue; the bulb was almost entirely excoriated, and in the anterior urethra were the usual enlarged follicles. Because of these findings, the patient was taken off all local treatment and submitted only to internal sedatives, with the result that in about a month all discharge disappeared, with the appearance of a few shreds. The source of these shreds would probably be corrected by giving, in due course, individual attention to the lesions named.

Periurethral pyuria in the male is well exemplified by the following history which shows the regard of careful examination:

**Case III. M. G.; Austria; white; aged thirty-nine years; married; tailor (case 12678); referred by Dr. Samuel Wechter, Pittsburgh, on October 23, 1912. Diagnosis, chronic suppurative prostatitis. Former venereal history negative as to syphils and other open lesions. Urethritis twice, last thirteen years previously, complicated by left epididymitis, funiculitis, and urethrocystitis, since which he had had relapses of chronic posterior urethritis. For this last attack he was treated privately for six weeks with internal and injection methods. Present venereal history through his physician stated that the relapses aforesaid were separated by periods of apparent absence of discharge. The first five glass tests of the periurethral showed shreds in the anterior urethral washings confirmed by a second anterior glass, the third glass contained heavy shreds from the posterior urethra, the fourth one clear, and the fifth or marginal showed many shreds and much pus again. These findings strongly suggested posterior urethral disease which on urethroscopy was found to consist in multiple sinuses in each, but most marked in the right lobe of the prostate, without any discharge, and slugs of pus into the field of the instrument. Smear and culture of the pus proved the presence of gonococci but the presence of Gram positive staphylococci and Gram positive diplobacilli. All uranalyses showed the absence of nephritis.

As distinguished from the foregoing case of chronic suppurative prostatitis with relapsing cystourethritis, is the following report of pyuria due to follicular prostatitis. In this case the diagnosis of pyuria was based on the fact that the pus was a factor on microscopic examination and only very rarely a microscopic factor:

**Case IV. H. S.; German; white; aged forty-six years; married; clerk (case No. 11757). Patient was first seen March 20, 1910. Diagnosis, third chronic anteroposterior gonococcal urethritis; sequel, chronic follicular prostatitis; incontinent sexual excitation. Family history: Father died of dropsy, mother living and well, two brothers dead as children, of diphtheria and meningitis, two sisters living and well, one dead of cancer. Wife without female disease of children, two miscarriages at about the fifth month of pregnancy caused by syphilis. Patient is a typical diphtheria, diphtheria and blood poisoning in youth without renal sequel. Weight, appetite, and bowels normal. Former venereal history: Patient denied syphilis, but had urethritis twice, the last attack in 1884, complicated with right epididymitis and probably prostatitis and urethrocystitis. He was treated by a physician in private for many months, during many relapses, with internal and injection methods, and finally discharged by the physician. Present venereal history: Had had intercourse with his wife every other day as a rule, more recently about once a week: no illicit intercourse. His third attack of gonorrhea began fifteen years ago, three days after intercourse, without evidence of recovery. For several months he has noticed a thin, moderate, purulent discharge, and scalding in the anterior and posterior urethra. No definite change in diurnal and nocturnal urination. Control has been doubtful and tenesmus present, occasionally severe. He had been treated by a physician in private, for a few months, with internal and injection methods, and had been discharged by the physician. Physical examination showed a man in good condition. Long mucous shreds in the first glass of urine, none in the second, third, or fourth glasses; sexual organ negative except for a decidedly soft prostate from which more shreds could be expressed. No residual urine except subjectively, when the scalding was most manifest. Urinalysis negative; pus negative; numerous pus cells and epithelial cells, few shreds; no gonococci in material from the urethra or from the prostate. The patient was treated conservatively and accepted means with little result so that a urethroscopy was done, which showed a very peculiar condition in the right prostatic sinus, namely, several very patulous follicles from which pus shreds could be seen extruding and in which a granulation was easily visible, while when the irrigation was passing into the urethra, receded into one of the follicles and when it was withdrawn reappeared much like a woodchuck at its hole. The man finally got well under conservative treatments, but would have been in these days of high frequency current applications an ideal case for this little granuloma. Even the older methods of urethroscopic treatment, however, served to relieve him.

Vesical pyuria is the next topic if we follow the logical sequence of passing upward from the urethra to the kidneys. The following case exemplifies the wisdom of early cystoscopic investigation when any pronounced disturbance of the bladder occurs, although there may not be blood or pus in the urine except perhaps in microscopic examination. Obvious functional disturbance merits a cystoscopic examination and would, if done very early for this man, have revealed the papilloma which came to light only when pyuria and one attack of hematuria convinced his physician that something must be done.

Under fulguration the papilloma is rapidly disappearing and within a month the man will be able to return to work; but these diagnoses should be reached long before these little growths reach the diameter of a cystoscopic field and long before they begin, perhaps, to infiltrate the surrounding bladder wall. As this patient does not speak English...
very well, the record is not as complete as desirable:

Case V. M. C.; Russian; white; aged fifty years; male; married; furrier (case No. 12881); referred by Dr. Benjamin T. Tilton and Dr. Ira R. Zippert of New York to the Clinical in Urology of Men, Women, and Children in St. Mark's Hospital O. P. D. Family history: Father died of age, mother of unknown causes many years ago, five brothers living and in good health, one dead of unknown cause. Wife, had had no female disease, and had had four children. Personal history stated that he had always had reasonably good health and had maintained normal weight up to this winter during which he had lost about twenty-five pounds. Formerly he had been a normal man, and had been about thirty years ago, without complications, and relieved by private medical treatment in one year. Syphilis and other lesions denied. Venereal history of present disease revealed no infections since youth and a rather active family sexual life. As far as the man knew he remained in good health until his urination seemed disturbed about three months previous to his first visits to the hospital in April, 1913. Massage of the prostate by his family physician appeared to have brought little relief and the patient himself prescribed the prop of a simpson. He then came to the clinic and was satisfied with remissions ever since. It might here be intersected that ordinarily prostate massage is best done on a full and not an empty bladder for the precise reason that the ureters are not distended by collapse of the walls upon the surface of the prostate within reach of the massaging or examining finger. The disturbance of the bladder previously spoken of was marked by the passing of ‘threads and pieces of flesh. These symptoms of the bladder accompanied the cystitis which was then appearing. They could hardly have been pieces of the papilloma, otherwise hemorrhage would have been a much earlier and more prominent symptom. Cystoscopy was recommended, accepted, and revealed a papilloma of the bladder in the vault slightly to the right of the median line in both the retro- public and subperitoneal quadrate. Its size was that of one cystoscopic field. Its general appearance was benign, except in that the papilloma protruded about the diameter of the patient’s right into the subperitoneal quadrate: an obvious nodulation, infiltration, thickening and inelasticity of the bladder wall were present. This, in the opinion of the writer and in agreement with other authorities, was strongly indicative of cancerous degeneration. A guardedly unfavorable prognosis had been given while treatment with the high frequency electrical current had been begun with very remarkable benefit so that after six applications the bleeding had largely disappeared, the tumor reduced, and urination returned to normal.

The involvement of the annexa will be thoroughly examined as soon as the extirpation of the papilloma is complete. It will therefore be noted that this is only a preliminary report of this case with the one object of showing how important may be the conditions behind early and seemingly unimportant bladder symptoms with pyuria as the first predominant symptom.

Ureteral pyuria is the next step and is well exemplified by a case which, although for several years in the hands of a well known general surgeon in New York city, was by him never submitted to cystoscopy after conservative measures had never relieved more than temporarily. It rests on one of the most peculiar abnormalities that the writer has ever seen in the living subject. In the nature of the case the history is not a very definite one, inasmuch as it doubtless passes back into childhood if it could be traced with sufficient detail.

Case VI. H.; about forty years old (case 12727); referred by Dr. Edmund P. Shelby of New York city. For at least fifteen years he suffered relapses of pyuria, accompanied by great depression of mind and nervous system and very pronounced overstimulation of sexual passion, so that seemingly his wife left him on this account. All the instincts of this individual were away from sexual luxury or excess, but his symptoms were obviously due to a pronounced organic condition of which he had no control and no knowledge. He was first seen February 27, 1913, in company with his physician who agreed that there was much about his urine to suggest widespread infection, with the choice resting on gonococcus, colon bacillus or tubercle bacillus. Frequent and studious laboratory investigation ruled out the first and the last and established the colon bacillus alone, which agreed thoroughly with another element in his history, namely, that his pyuria and insanity were usual symptoms of a syphilitic infection. This fact must be at the basis of his mental depression and the augmented infection of the upper urinary tract at the basis of his sexual disturbance. It was endeavored to control the pyuria with equal doses of antiseptics, but without success. A cystoscopy was then undertaken, revealing a bladder obviously the seat of long continued moderate cystitis and lateral to each ureter what seemed to be the narrow mouths of diverticula of the bladder. These were proved, however, with the ureteral catheters to be double ureters with the following general features. The pair of openings nearer the middle line were normally placed for the ureters and admitted the catheters with reasonable ease. Sixty-five years ago, twenty to twenty-five centimetres. The abnormal ureter on the right side could be penetrated for almost an equal distance while that on the left side accepted the catheter for five centimetres, then turned in on itself and passed the prostate, where it would have indicated this to be a diverticulum were it not for the fact that what seemed to be urine was seen to flow from each abnormal opening. Separation of the urine was now undertaken and showed from the right the normal urine except for pronounced colon bacillary bacteriuria with exfoliation of probably ureteral cells. The right accessory ureter showed a similar result. No change in the urine between the right and left normal ureters was made out, and the left accessory ureter was useless but the penetration of the catheter was too slight to permit a specimen to be obtained. Dr. Lewis Gregory Cole, of New York, kindly performed the radiographic study of this case with the following eulogistic March 17, 1913. From this study of these plates there is evidence of two clear cut, well-defined shadows on the right side, near the lower end of the ureter, and one on the left side. These shadows are small and round, and have the appearance of phleboliths, rather than ureteral calculi. I do not believe that one is justified in stating with certainty whether these are in the ureter or outside of it.”

This radiographic analysis also rules out stone in the kidney or upper ureter, floating kidney with kinking of the ureter, pyonephrosis, hydronephrosis, neoplasm, and tuberculosis of the kidney. The uranalysis established the fact that there is no active disease of the parenchyma or pelvis of the kidney. We are now thrown back to the diagnosis of colon bacillus infection of the normal and abnormal ureters and bladder, subject to relapses which in themselves rest on his intestinal condition. His family physician has maintained control of the case and has been adverse to further radiographic pictures with X ray catheters in the ureters in order to demonstrate the exact pathological anatomy of the parts. It is to be regretted that such a final showing cannot be given, as the case is extraordinary and suggests one of the limits one may reach by patiently continuing to examine until a valid ground of pyuria is reached.

We now ascend one step in the anatomy to the pelvis of the ureter and the kidney and have to speak of the pyuria due to such conditions as hydronephrosis which in early degrees is without material effect on the kidney. The diagnosis of hydronephrosis in the following case is strongly suggested by the facts in hand, but never fully proved because ureteral catheterization done in the writ-
er's office with the greatest possible precautions provoked profound renal disturbance lasting several weeks. Even when the kidneys are the seat of hydronephrosis it may take very little to induce untoward effects.

Case VII. L. A. S.; American; white; about forty-five years old; female; widow; nurse (case No. 12682); referred by Dr. A. S. Holcomb, of New York; first seen in October, 1912, in chronic misdiagnosis; hence entered in June, 1913. Diagnosis, moderate relapsing hydronephrosis of the left kidney. Family history negative. Present history concerned of relapsing pain on the left side more or less accentuated and associated with attacks of pyuria chiefly of the microscopic rather than of the macroscopic type. On physical examination no mass could be made out in either kidney region, only a little muscular rigidity on the left side and a sense of fulness. No mobility of the kidney determined. Ten uranalyses on this patient were made some of which were supplied for me by Doctor Holcomb. When twenty-four hour specimens were taken the range was from thirty-five to seventy-two ounces. Odor and color normal without turbidity. Reaction was ranged from alkaline to alkaline in two of the twenty-four specimens, which may have been due to early decomposition. The specific gravity ranged from 1.006 to 1.018, some of the lowest occurred in the twenty-four hour specimens. Chlorides normal. Urea ranged from nine tents of one per cent. in one of the twenty-four hour specimens to two and two tenths per cent. Uric acid when recorded excessive. Indican varied from normal to excess. Acetone was present once. Glucose, biuret and diazo reactions all negative. Albumin present three times, to the ordinary and to Eabc's tests, but always too little for quantitative determination. Serum globulin and albumoae absent. Microscopical examination showed a tendency toward phosphaturia twice, and a great excess of oxalates from superaline acid and granular casts were present once; epithelial casts six times. Pus in distorted cells or slugs, usually in very large amounts, was absent only twice. Blood was present once; various bacteria four times without definite identification. Many collected the same general rule as the pus but in much smaller amounts.

A negative x ray was taken on this patient.

June 8, 1912, a phenol sulphophthalieine test of the combined kidneys was performed in the following manner: At 10:10 a.m. she drank one pint of water. At 10:25 the bladder was catheterized and one ounce of urine withdrawn, whose general character differed in no respect from the ten specimens previously analyzed and just discussed. At 10:30 a.m. 0.0 c.c. of the dye was intravenously injected. At 10:45 specimen No. 2 containing one ounce of urine was collected. Hyaline and granular casts were present once; blood several times. The six specimens of urine were collected at intervals of time and twenty-seven per cent. were found in specimen No. 3 containing five ounces withdrawn at 11 a.m.

June 19, 1912, catheterization of the ureters was performed with the following result, the bladder being itself negative to cystoscopy:

CATHETERIZED SPECIMEN. JUNE 19, 1912.

Subsequently it was decided to measure the capacity of the renal pelves which was done in consultation with Doctor Holcomb and Dr. Ira B. Terry. The ureters were readily catheterized and the right kidney was first tested. After about fifteen c.c. of warm boracic acid water per cent. were run in with the greatest gentleness the patient complained of distress, and this quantity was accepted as the normal capacity of this pelvis. The left pelvis was now investigated, but the patulousness of the ureter allowed so small leakage that about 200 c.c. were injected without sensation to the patient except that of fluid in the bladder. The patient was then sent home with the purpose of repeating this test at a later date using a full size catheter of the left side. She underwent, however, a very tender disturbance with chills, fever, and oliguria and was confined to bed for three weeks. At times her condition was serious. At the time of the report the woman was doing extremely well under Doctor Holcomb's care with purely expectant treatment, chiefly urinary antiseptics and diet. The diagnosis in this case was by no means definite. That it was pelvic rather than renal was suggested by the uranalyses. That it was of the left side was insisted by the patient on account of the fixed pain there and indicated by the cystoscopic examinations which revealed that left more than the right ureter was abnormal. That both kidney pelves might be involved was shown by the somewhat greater amount of pathological elements obtained by cathe- terization from the right than from the left side, and by the cystoscopic reaction after the capacity test of the pelvis which seemed focalized on the right side. The negative result of the x ray test was unfortunate. One might say that this woman had a hydrourephrosis on the left side indicated by the absence of sensation when the fluid was being run into the pelvis of her kidney, and a lithiasis of the right side suggested by the irritability there. Only time will settle these questions with one or more investigation of the case.

The last example is that of renal pyuria exemplified by the following very interesting case which had a fatal issue after nephrectomy, due to universal infection of the wound with Bacillus coli. The error which the patient made was in considering his pyuria as a relapsed gonococcal urethritis so that he postponed all medical advice for several months for shame, and in postponing the operation, by reason of fear, for nearly six months during which the infection of the kidney, ureter, and bladder had extended.

Case VIII. A. H.; German; white; aged twenty-seven years; male; married; printer. (Case No. 12684). First seen in the present illness November 12, 1912. Family history: Both parents, four brothers and three sisters; living in good health, no deaths: wife well, one child well. Personal history: Good health; diphtheria in childhood, no renal disease known; weight 133 pounds constant, and
standard; appetite good; bowels irregular. Former venereal history denied. Present venereal history: Sexual habit irregular; last infection four and a half years ago; incubation two weeks; duration seemingly off and on since infection. No recent symptoms except scalding, which was occasional. One of the urinary passages nourished urination nocturnal four or five times. Control is slight and variable, likewise urgency and tenesmus. No blood before, after, or with the urine. Last intercourse with his wife three months ago; since then the last pyuria was beginning. Previous to this his urination was four or five times by day, and none at night. During the acute stage of his urethritis, four and a half years ago, he had treatment for eight weeks with internal injection and irrigation methods. The urine contained much pus and urobilin. He worked as a Jew in good general condition; no urethral discharge, but much pus in the first and second glasses of urine, suggesting tuberculosis.

Fitch's case history was as follows: Pain referred chiefly to the penis, across the base, seemingly of bladder origin. Had not had intercourse with wife or other woman for three months, through fear of infecting her. Could not state relation between pain and coitus, or defecation. Frequency of urination by day, at least every two hours, sometimes every hour; by night, several times. No change in this symptom. Stream, said to vary, at times small; no obstruction. Had not noticed pus in the urine subjectively. Specimens at first visit filled with it. Blood, not noticed subjectively, were rare. His history extended from December 1912, and March 26, 1913, and April 17, 1913, and again at St. Mark's Hospital on admission. Tubercle bacilli were found in all specimens except the third by different laboratories. He had a catheter inserted September 29th, did not show bacilli. The first cystoscopy was done on November 23d, as follows: Free irrigation removed pus. Instrument introduced with very little distress. General condition of the bladder showed no diffuse nor disseminated congestion, no tubercles nor ulcers. Right ureter seemingly normal though slightly patulous; no zone of redness about it. Left ureter seemingly elevated, restricted, and patulous in a panoramic elevation of the bladder, apparently within its course; a sort of redness slightly to the left and behind the opening and flakes of pus. Suggested diagnosis: Tuberculosis of the kidney.

Ureteral catherization on the same date with phenol-sulphonephalein injection showed only 27.5 per cent., exacted by both kidneys combined in about one hour, but the right kidney output was double that of the left. The patient continued to collect the urine at home after this test for twenty-four hours, but could show only 2 per cent. additional, perhaps because the dye was destroyed in his body. December 1912, January 1913, was as follows: Cystoscopy introduced with no spasm and little pain. Condition of the bladder as a whole much as it was at the previous cystoscopy. Around the left ureter were a number of whitish, whitish, irregular, drop-like, coccic, and tubercles. The mucous membrane itself was not greatly congested but the opening was patent (golf hole) and retracted so that ridges seemed to run into it. Strings of mucopus were seen slightly gravitating out of it. On January 14, 1913, Dr. Lewis Gregory Cole made a radiographic examination of the case, as follows: *Plates of both kidneys, left ureter and bladder, show the ribs, spine, transverse processes, spine of the ischium and coccyx distinctly. The left kidney shows distinctly as the adult, normal in size, shape, and position, and shows no irregularity of density or contour. The right kidney is somewhat obscured by an accumulation of gas and feces, but the plates show sufficient detail to justify us in making a negative diagnosis of a calculus. The plates made after the intravesical injection, show the spine, pelvis, cystoscope, and catherizer distinctly. I am unable to detect any evidence of the argyrol in either the kidney or ureter. The plates showed one feature, namely the presence of a pale submucous, irregular outline of the bladder, which was found whenever catherization was attempted. In April, 1913, a consultation was held with Dr. L. B. Bangs and Dr. James Pedersen, and his family physician, Dr. Marcus Goodman. The cystoscopy then showed extending cervices and a large portion of the bladder, which was removed. Operation was recommended, but again postponed by the patient. During the long period of hesitation as to operation, the patient was given ascending injections of tubercle bacillus, emulsion strictly after the method of Trudeau. Health and strength were kept up by the best possible hygienic and dietetic measures. Urinary antiseptics were freely used. After awhile the patient disappeared, went to one of our large hospitals, underwent cystoscopy, and was admitted for operation, but became dissatisfied, and returned to the writer's hands. On June 12, 1913, nephrectomy was done in St. Mark's Hospital with the aid of Dr. Benjamin T. Titon as consultant. The left kidney was rapidly and easily exposed along the dorsal surface and the ureter isolated and dissected out as far as the bifurcation. The bladder was found as thick as an adult middle finger, was divided between two clamps and used as a guide to the pedicle. This early division of the ureter proved to be a mistake, as it served to inject the wound from end to end in this very detail of using it as a retractor. The wound and wound upward a puncture of the diaphragm which occurred which opened the pleural cavity. This was carefully closed with banked suture and, except for rapid respiration during the convalescence, the collapsed lung caused no trouble and began to expand again until the patient, by getting out of bed, reopened the wound. The pedicle was easily found, clamped, divided, and tied. The wound was very carefully dried and cleansed, a catheter passed to its deepest part and then firmly closed, first because the patient desired this, but as he had a relative who for an indefinite time had had a sinus after a nephrectomy and because it was desired to follow the recent teaching of the Mayos. Nearly a quart of normal salt solution was run into the wound, a copius dressing applied without drain, and the patient returned to bed. From the outset of the recovery the fear which the patient had of the operation redoubled itself and he tossed about the bed, got up once and wanted to go home, and otherwise he wore down his strength so that when the infection appeared, due to the premature division of the ureter, he was a very poor subject to resist it. He died on the tenth day after the operation of bacillus coli infection which converted the wound into a foul fecoidal pocket. At the first sign of this, widespread drainage was instituted, but failed to save the patient.

This patient lost his best opportunity in passing from the period when his bladder showed no tubercles and his urine contained bacilli to the period when ulcers in the bladder had appeared and the kidney had been transformed into several large abscess cavities, so that it was only with dexterity, gentleness, and time that the organ was removed without rupture.

These several cases have been presented as types of pyuria proceeding from the various anatomical portions of the urogenital tract in males and females. Cases of some difficulty were chosen because it is precisely from these that one gains most in study. If the members of the society concur in this opinion, then the preparation and presentation of this paper has been both an honor and a reward.

45 West Ninth Street.

THE THEORY AND TREATMENT OF DIABETES.*

BY WILLIAM E. FITCH, M.D.

New York.

About one year ago I began a clinical investigation on the further study of diabetes mellitus, more particularly its control by dietotherapy. I inserted a card in more than one hundred medical journals requesting information from the profession as to the possibility of obtaining a diet containing a liberal starch allowance. I received more than one thousand replies reporting experiences with various remedies. Fifty-seven and one half

*Read before the Medical Association of the Greater City of New York, October 26, 1913.
per cent. agreed with von Noorden that "the best treatment for the diabetic is the food containing the greatest amount of starch which the patient can take without harm": eighteen per cent, pinned their faith to gluten bread and gluten products; 7.5 per cent. used drugs and paid no attention to diet, while seventeen per cent. used both drugs and diet. The consensus from these correspondents was that the present methods of treatment were unsatisfactory to both physician and patient.

Laboratory work upon diabetes during recent years, and a more careful study of its metabolic disturbance, have taught us many new facts, particularly from the dieterapeutic viewpoint which had been thought to be the true one, but in the light of later research has been materially modified. Therefore, what to many may pass as the newest standpoint is abandoned by others in favor of a still newer one. Von Noorden, one of the best known authors on this subject, has stated that opinions which have prevailed for two decades concerning the theory of diabetes can to-day be no longer maintained.

THEORY.

There is no subject in medicine upon which have been contributed so much thought, time, and energy, from an experimental standpoint, as diabetes, and yet no subject as to the true pathology and etiology of which we possess proportionately less accurate information. For the sake of convenience we will refer to three types of diabetes: 1. Cases due to lesions of the fourth ventricle; 2, cases due to metabolic disturbances of the liver and alimentary canal; 3, cases due to pancreatic disturbances (atrophy of the islands of Langerhans).

Cases under classification 1, while rare, are often puzzling to the physician, as all of the accompanying brain symptoms are frequently absent.

Cases under classification 2 are the most common forms of the disease met with. Here we have two broad types: (a) the patient is usually stout, very fond of food and usually termed a "high liver," and inclined to a sedentary life; (b) the second type of class 2 is found in a person of ordinary build, whose urine is free from uric acid sediment, but who suffers from skin complications, itching, boils, carbuncles and gangrene.

Cases coming under classification 3 are due to an acute process in the pancreas, where the pancreatic ferment does not exercise its normal function. This type of the disease is frequently observed in children and in adults of the working class. Patients of class 3 suffer from great thirst, marked emaciation, and voracious appetite; they excrete large quantities of urine, loaded with sugar.

While the foregoing classification, for the sake of convenience, is referred to as types of diabetes, we do not wish it inferred that we believe the diseased process is confined to any one organ, for no organ "works for itself alone. It depends on processes going place in other organs together with the production of its own activity, which influence the function of other organs. These products may be ferment stimulating decomposition in the blood, or Diapor as regulating activity of the cells. Albumin, Bile stimulating decomposition in the blood, or iron have tended to confirm the importance of the part played by the internal secretion of the pancreas in carbohydrate metabolism. In an examination of the pancreas in 183 cases of diabetes, Weichselbaum found in every one distinct and characteristic lesions in the islands of Langerhans. Complementary to this, in an even larger number of control cases representing many different diseases, no corresponding changes were found.

I am not prepared at this time to discuss the question as to the extent to which lesions of the pancreas are responsible for the condition of diabetes; it cannot be gainsaid, however, from the phenomenon which follows extirpation of the pancreas, that disturbance of the function of the pancreas can lead to diabetes. The only question is: What is the manner of action of this organ whose absence leads to diabetes? Recently it has been suggested that the rôle of the pancreas should be otherwise regarded. The action of various organs having internal secretions has been exactly determined, and it has been found that many organs, such as the thyroids, parathyroids, adrenals and the glandular lobe of the hypophysis influence not only the metabolism of protein and fat, but also exert a special influence modifying the behavior of carbohydrates in the organism.

From the foregoing conception, Minkowski (2) believes the liver directly controls the metabolism of carbohydrate, for excess of carbohydrate is deposited in this organ in the form of glycogen, to be converted into sugar as required. This activity is regulated by the adrenal system and the pancreas. The secretion produced in the adrenal glands accelerates sugar production. The pancreas on the contrary inhibits the production of sugar in the liver. Injections of pancreatic ferment remove the inhibition over sugar production, allow unrestrained action on the part of the adrenals upon the liver resulting in the most aggravated types of diabetes. Minkowski (2) in discussing this point, says: "I certainly will not deny that other organs may contribute to regulate carbohydrate metabolism and therefore may have an influence upon diabetes." It is believed that the adrenals contribute directly or indirectly to the mobilization of sugar, the thyroids help to increase protein metabolism, although they may also act in other ways to increase sugar formation.

Cammidge (3), discussing The Relation of the Ductless Glands to Glycosuria, says: "The glycosuria, seen after extirpation of the pancreas, may be looked upon as a negative pancreatic diabetes and a positive adrenal diabetes, for the normal inhibitory action of the internal secretion of the pancreas is removed while the mobilizing power of the adrenal secretion is increased by hyperfunction of the chromaffin tissue."

The influence of the nervous system on carbohydrate metabolism has been recognized since the days of Claude Bernard, and there can be no doubt that nervous disturbances enter into the pathology of many cases of diabetes.

A number of toxic influences possibly act in a similar manner, the glycosuria to which they give rise being partly a result of the action they exert on the diabetic centre in the medulla, and partly an effect of their stimulating action on the sympathetic
nerves, or on the suprarenals directly, thus, in case, causing hyperfunction of the chromaffin system, with consequent overproduction of sugar by the liver.

As to the application of the theories to diabetes, from what has already been said, it will have been noticed that there is a tendency at the present time to revert to the doctrine that overproduction of sugar is the main cause of diabetes, and to abandon the element of this view which is held by a number of eminent observers, including von Noorden (4), who consider that the hyperglycemia, and consequent glycosuria, is due to an excessive output of sugar by the liver, and that this may arise from excessive stimulation or impaired inhibition. The stimulus to the liver may come from an excess of carbohydrate food, as in alimentary glycosuria, from an increased call by the tissues, from hyper-function of the suprarenals, etc., or from the central nervous system through the medium of the chromaffin system. Impaired inhibition may arise from suppression, or impairment, of the functions of the pancreas, or from interference with the controlling action of the thyroid or hypophysis on that organ. In some cases also there is probably a preliminary anomaly of the liver cells themselves.

The views that are at present held with regard to the interaction of the ductless glands and their part in the production of diabetes are to some extent theoretical. This is particularly so as regards the chromaffin system, but they correlate in a much more satisfactory manner than has previously been possible to the experimental data that have accumulated as to the effects of these organs on carbohydrate metabolism, and they bring into line the known facts in the etiology of diabetes. Whether subsequent observation confirms, or in part disproves these theories, there can be no doubt that they open up a wider conception of the interaction of the ductless glands. With a better understanding of the theory of the origin of diabetes and a more thorough study of the metabolism of a diabetic, there has come a reaction from the severe restriction in the use of starch foods, favoring a more normal balanced diet.

CARBOHYDRATE METABOLISM.

Metabolism is the all important factor in the maintenance of life and health. Heat and energy become absolutely necessary in order to convert the nitrogenous or protein elements into protides and thence into tissue and fat. In order to get this heat and energy, the body burns carbon and thereby gets the heat, while the energy is supplied as the direct result of combustion of water contained in the starch elements. Pavy is right in his assertion that in healthy digestion the carbohydrates (starches) and sugars are converted, not into glucose, but into maltose C_{12}H_{22}O_{11} (dextrine being intermediate in composition). Maltose is absorbed and assimilated—converted into glycosen. For the proper production of maltose and its ready assimilation a healthy venous blood carrying a maltose favoring hormone ferment is necessary. In the process of digestion starches are converted first of all into alcohol before work on the rehabilitation of the organism can begin. We know that any food becomes an irritant when taken in excess above a legitimate demand; therefore carbohydrates containing starch (untreated) given in great quantities to a diabetic will produce an irritating effect upon the sugar-producing organs; as a result the patient will suffer from glycosuria. It is regrettable that so little is known of the pathology of this malady. Textbooks and current medical literature contain little or nothing on the subject that is new.

Why does a diabetic void sugar in his urine? The answer is, because of faulty carbohydrate metabolism, the patient is not able to convert the sugar into alcohol in his system. The reason he cannot is at present unknown to physicians and pathologists. This much is certain, however: If carbohydrates are withdrawn from his dietary, the patient will feed on himself until all the fat stored in his system has been consumed, and then he will die. While we know that alcohol has its abuses, yet we cannot live and have our being without alcohol in our system. We understand that all starches are first converted into alcohol before they can yield their energy to the system, and a certain amount of alcohol is necessary for the conversion of nitrogenous food into tissue building material to sustain the human economy.

TREATMENT.

The treatment of diabetes is far from ideal; being a malady subject to varied complications, it necessarily presents a difficult problem in treatment. We recognize that it is primarily a disturbance of nutrition in which the function of utilizing carbohydrate foods is more or less completely impaired. No disease with which I am conversant necessitates such a careful balancing of all the details of each individual case. The metabolic powers of the patient, the functional condition of the liver, the condition of the alimentary tract, the state of his nervous system and of his environment, and the functional capacity of his pancreas, must be severally and collectively considered in forming a conclusion as to the advice that should be given him for his daily conduct in the future. From the varied accumulation of theory, research, experiment, and observation which go to make up the medical history of this disease, we find when winnowing the chaff from the good grain that diabetes mellitus in man free from grave complications is amenable to satisfactory treatment, in fact is easily curable in proportion to the accuracy and persistency of the treatment, as well as the honest cooperation of the patient. Kolopinski (5), in discussing this phase of the subject, says: "Diabetes is a disease curable by diet, therefore dietotherapy is the remedy par excellence in the successful handing of this malady.

The newest researches have taught us that the manner in which carbohydrates are allowed is of the greatest importance. It is, therefore, the bounden duty of the physician carefully to study his patient in order to determine just the kind of carbohydrates his patient can tolerate and the method of preparation best suited to his condition in order that he may be allowed the greatest amount possible without increasing the output of sugar. The human body obtains its energy and nutrition from three types of foodstuffs, proteins, fats, and carbohydrates. For general purposes of
work, warmth, and nutrition, all three serve well; the muscular tissues are, however, most specific in their requirements. They have a predilection for sugar as their foodstuff and immediate source of energy. It is necessary, therefore, that sugar should always be available for this purpose. The liver, with its sugar factories—the liver cells—fulfills this function.

It is a well-known physiological fact that all of the carbohydrates of food are converted into sugar in the intestine and carried to the liver in such a special protection, however, exists for the prevention of an excessive flow of sugar into the blood after a large meal of carbohydrates. The liver takes up the sugar as it arrives and stores it in the liver cells, where it is instantly changed into an insoluble form of sugar, known as "glycogen," to be used as a reserve material. This storage of carbohydrates as glycogen and the further change of glycogen into sugar is not all of the work the liver does. Human beings consume various kinds of foodstuffs other than carbohydrates; therefore the liver is compelled to make sugar from other materials—albumins, fats, and proteins, which under certain conditions are used by the liver for the manufacture of sugar.

Carbohydrate treatment. Various carbohydrate cures have been recommended in diabetes. The oatmeal cure by von Noorden, the rice cure by von During, the potato cure by Mosse and others; but experience teaches that none of them can be relied upon. The best perhaps is the oatmeal cure, which according to Blodgett (6), of Boston, can only be used at stated periods, "carbohydrate days," and then he recommends the oatmeal to be cooked for about seven hours. The long continued cooking no doubt produces changes in the starch atoms, which accounts for its virtue as a diabetic diet. Strauss (7), in discussing the various carbohydrates cures, says their beneficial effect can be attributed to the absence of animal protein and to their low caloric food value, and he believes that they are practically starvation cures. He says that when carbohydrates are given in small amounts distributed throughout the day, they do not produce as marked glycosuria as when taken in large quantities, consequently the essential feature of the carbohydrate cures is to give the carbohydrates in small repeated amounts. Strauss does not believe in giving a mixture of different starches, but adheres definitely to a simple form of carbohydrate, asserting that better results are obtained when the carbohydrate is given alone than when combined. He advocates carbohydrate days kept up for a short period of time, stating they furnish less than the required amount of protein. He disbelieves that when the required amount of protein is attempted to be made up by the substitution of various vegetable proteins for the loss of animal protein, the experiment has been successful.

As to the dangers of a starch free diet, the general experience of practitioners (8) is now that too strict a diet is not desirable, except in very severe cases, and in those only for limited periods at a time. Diet, like opium, may control the symptom glycosuria, but it does not remove the condition, and it may help to kill the patient by impairing the general nutrition and by bringing on diabetic coma. In determining the proper diet for a patient suffering from diabetes, it is irrational to commence the treatment by cutting out from the daily dietary all carbohydrate foods. Each case must be carefully considered with regard to the possible cause of the sugar in the urine. Errors in diet, such as overeating, may result in a temporary glycosuria, and such cases do well on a carefully restricted diet. There are other cases of diabetes which certainly do not improve, but undeniably become considerably worse on a diet free from carbohydrate food.

Professor Osborne (9), of Yale Medical School, says: "I have no doubt that many a patient with diabetes mellitus has been hurried to his grave by a rigid starch free diet. I also believe that the fact that most so called starch free gluten foods contain starch has permitted many a diabetic to live months longer than a starch free diet would have allowed.

An absolute withdrawal of carbohydrates from the foods of patients having true diabetes mellitus will always increase the acetone and diacetic acid and often the ammonia and betaoxybutyric acid and toxic acidemia and coma become imminent. Hence, it is unjustifiable, sugar having been discovered in the urine, to withdraw the starches absolutely or too rapidly from the diet."

Sajous (10), in discussing the diet of diabetes mellitus, states: "Hyperactivity of the test organ and its adrenothyroid center is the direct factor in the overproduction of sugar; the prevailing method of depriving the patient of starches and sugars is unscientific. The morbid process being an excessive consumption of these substances in the body at large, including the hepatic glycogen, their withdrawal from the food can have but one effect, viz., to place at the mercy of the amylolytic triad of the blood what carbohydrates remain in the tissues. The body is thus depleted as far as possible of physiological components of the highest importance to its welfare. The sugar in the urine naturally diminishes, and may even disappear; but this does not prove in the least that the disease is counteracted; it only shows that the patient has been drained effectively of his main sources of muscular energy and heat. Nor does the meat diet to which the patient is relegated even protect him against the renal complications feared, since glycosuria is known frequently to persist under such a diet and to promote the appearance of acetonuria and acidosis. This abstinence from starches, sugar, etc., is harmful under such conditions, as shown by the fact that the restoration of carbohydrates often causes both acetonuria and acidosis to disappear."

Doctor Stark says (11): "A rigid exclusion of sugars and starches in the treatment of diabetes is a thing of the past, nor do we often find it necessary to exclude them permanently from the menu of diabetes. On the contrary, we often substitute carbohydrates for fats in cases of marked glycosuria. As a matter of fact, the organism actually requires for its maintenance carbohydrates for the repair and growth of its tissues and for the production of heat and muscular force. This necessity for carbohydrates is so emphatic that directly they are prescribed the system draws upon the nitrogenous element of food to supply the mis-
ing component." As to the influence of meat, Crofton (12) states "that in many cases it is well known that the sugar excretion stops only when the amount of meat is considerably reduced. Further, it can be shown that withdrawal or reduction of meat appreciably increases the tolerance of carbohydrates." He urges, moreover, that "the chief danger incident to withdrawal of carbohydrates is acidosis and coma and also that "it is surprising how often the administration of a little carbohydrate in cases that are on rigid diet, or of some more carbohydrate in cases that are receiving only small quantities of carbohydrate; will cause all these dangerous phenomena to disappear."

During the past twenty years I have had much experience in both private and institutional practice in the treatment of diabetes. I have used gluten foods and gluten flour, and have come to the conclusion that the only virtue in the gluten products depends upon the large percentage of starch they contain. Many of the gluten foods have been found to contain as much starch as ordinary bread taken from the corner bakery, and in some instances the percentage of starch was even higher. I have tried the rigid starch free diet, only to be disappointed. I have prescribed the various carbohydrate cures, the oatmeal cure, the potato cure, the rice cure, etc., in various types of the disease without satisfactory results either to myself or to my patients.

Unfortunately, pharmacology has not provided any drug which acts directly upon the sugar forming process of the liver. Therefore, properly selected diet is more efficient than any drug or combination of drugs offered for the treatment of this malady, and offers the greatest and most rational promise of relief or cure, and is undoubtedly the sheet anchor in the treatment of diabetes. Von Noorden (13) and other eminent authorities aver that the best food for the diabetic is the food containing the greatest amount of carbohydrates which they can tolerate, because in the carbohydrate is contained the greatest proportion of calories or heat units, which go to make up the energy of life.

During the last two years I have treated a series of patients on a carbohydrate food manufactured from wheat and barley cereals. The grain is ground on the old fashioned buhr millstone, and the finished flour contains all of the starch and cereal salts that Nature grew into the grain in the field. After being ground, the whole wheat flour is subjected to a series of special processes brought about by the application of a certain degree of heat for a specified period of time, which causes certain changes in the starch atoms. It is estimated that a grain of wheat contains one hundred million starch atoms, only a small proportion of which is broken up in the process of grinding. This special treatment by the application of heat produces changes in the envelope of the starch atoms which facilitate digestion and assimilation. I personally believe in allowing diabetics carbohydrate, together with nitrogenous food, sufficient to build up and maintain the human economy; but starch and nitrogen per se mean nothing toward sustenance until the animal economy has converted these elements into tissue building material. Among the many advantages of starch treated foods is the fact that they indirectly facilitate the absorption of other foods, especially carbohydrates of every kind, on account of the apparent indigestion they seem to hold out to the enzymes of the intestinal tract, to assume their full amylolytic function with promptness and thoroughness. I have treated a great number of cases of various types of diabetes by prescribing these starch treated foods to the exclusion of all other starch foods, and have been very much gratified to see the percentage of sugar in the urine gradually decrease and finally disappear.

THE PHYSICAL, MENTAL, AND MORAL VIGOR OF OUR SCHOOL CHILDREN.*

Fragmentary Notes on How to Preserve and Increase It.

By S. ADOLPHUS KNOPF, M. D.

Professor of Medicine, Department of Physiotherapy at the New York Post-Graduate Medical School and Hospital.

(Concluded from page 1101.)

20. Vaccination against smallpox should be a requisite to admission to any school, public, parochial, or private, and periodical revaccination, particularly in times of epidemics, obligatory to continued attendance at school.

Parents objecting to vaccination should be obliged to maintain their own schools. It would prove the best propaganda for compulsory vaccination. An additional and effective means to educate antivaccinationists and to convince them of their folly is to send them the authentic records wherein it is shown that in epidemics the nonvaccinated individuals have died and the vaccinated ones survived. A good authoritative statement to give to the antivaccinationists is the following: In Germany, where vaccination has been compulsory for many years, there has only been an average of fifty-three deaths annually from smallpox, while in Russia, where there exists no compulsory vaccination law, for the same population there have been forty thousand deaths from smallpox annually. There is virtually not the slightest risk from a careful antiseptic vaccination against smallpox made with pure virus. Thus, for example, in the Philippines two million vaccinations were made without a single case of serious infection. But we need not go to the Philippines or foreign lands for a lesson. In a health

*Read before the Fourth International Congress on School Hygiene, Buffal0, August 27, 1917.
against this disease. It can be curtailed by symptomatic treatment and constant outdoor life for the patient. It should, however, be remembered that vaccination against smallpox has been benificent as a means to cure whooping cough. It has long been a well known fact that children who were vaccinated about the time they were coming down with whooping cough soon stopped coughing and in a short time recovered completely.

33. All hindrances to the proper physical and mental development of the pupil should be remedied, such as adenoids, enlarged tonsils, polypi, or deviated septum, defective eyesight or hearing, defective teeth, and orthodontial treatment for the correction of irregular teeth should not be neglected. The same should hold good for the treatment of any remediable unesthetic appearance in the child.

In children, and particularly young girls, a deformed jaw or nose, or irregular teeth are distressing to both mother and child. Because orthodontial treatment is long, tedious, and expensive, few of the poor can avail themselves of this modern advance in dental therapeutics. Even boys like a straight jaw and straight teeth. Where municipalities hesitate, or for reason of economy cannot undertake to remedy the unesthetic appearance of the child of the poor, philanthropists, well to do men and women with or without children, should come to the rescue of these poor unhappy ones.

34. The home environments as well as bad school hygiene are often responsible for the pupil's physical or mental inferiority. Underfeeding, unsanitary sleeping quarters, child labor at home, or lack of sleep are often the cause of physical or mental deficiencies.

Upon the request of a teacher the superintendent should have a right to investigate the home environments of any pupil to determine what is at fault. The reason for the child's mental or physical inferiority may thus be discovered. Many parents feed their children badly, not always because of want, but very often because of ignorance and thoughtlessness. The same thoughtlessness and ignorance are often responsible for the lack of sleep. Children at the age of four ought to have at least twelve hours sleep; from five to seven, about eleven hours; from eight to nine, ten and one half hours; at eleven, ten hours; at twelve, about nine hours. The more regularly children retire, the more refreshing will be their sleep and the better their health.

35. All medical, surgical, and dental treatment should be provided for in such a way as not to pauperize the recipient.

Parents should have a right to choose their physician, surgeon, or dentist as long as they are willing and able to pay for their services. Such arrangements are essential. Too much paternalism is resisted, and justly so. A tactful letter from the school physician will remove all friction.

36. Suitable luncheons should be served at cost in properly equipped lunch rooms at the school.
house. This will help the underfed, the carelessly fed, and the anemic child. Table manners should be taught and helpfulness and democracy inculcated by having the children alternate serve each other.

No one who has studied the effect of serving luncheons at school can possibly doubt the inestimable value of this innovation. In New York city a special examination of 2,051 children at the public schools was made by the board of health physicians. Over fifteen per cent. were found to be suffering from malnutrition. These were only the children in the lower grades of two of our public schools. In ten per cent. of the cases investigated the mothers were a wage earner and not at home to prepare the noon meal. Of children taking luncheons last year, seventy-three per cent. were from families having an income below the living wage. Thirty-three per cent. were from families of five having an income of less than ten dollars a week. The results of serving luncheons at school for the first three months were as follows: The undernourished children were weighed at the beginning and again at the end of the period. It was found that the children taking the lunch had gained three times as much as those not taking it. The principal of one of the schools in which luncheons are being served says: “The work of the School Lunch Committee has demonstrated without a doubt that in many cases where the child has been unable to do his school work properly it has been due to insufficient nourishment; an immediate and marked improvement having been shown since the child has been provided with a hot noon meal.” For the guidance of those desiring to imitate the school luncheons let me give here the menu for one week in the New York schools:

Monday.—Rice and tomato soup and bread.
Tuesday.—Mashed potatoes and meat gravy.
Wednesday.—Pea soup and bread.
Thursday.—Lentils and rice and bread.
Friday.—Potato soup, croutons, and bread.

In addition to this three cent meal, a child may buy for one cent either cocoa, sandwiches, crackers, a salad, cooked fruit, or other nourishing food. In many of the schools each article of food is sold for one cent in preference to a three cent luncheon. Where investigation has shown that the parents of a child are unable to pay for luncheons, or that it would be a serious hardship, meal tickets should be given to the children, but in such a way that neither they themselves nor their fellow classmates should know that it was charity. In Miss Denison’s book, already referred to, there is another chart (Fig. 4), which indicates that out of 100 undernourished school children, three per cent. only are provided with luncheons.

37. Sanitary fountains furnishing good, cool water should form part of the equipment of every school, and the drinking of plenty of such water should be encouraged.

Many of the discomforts of the children can be traced to the insufficient ingestion of liquids. It goes without saying that if there is no sanitary fountain, the individual drinking cup which the children can make themselves from paper is the best means of avoiding infection which has been so frequent with the old fashioned common drinking cup.

38. No public school should be considered well equipped without its swimming tank of running water; no curriculum complete without swimming lessons.

Aside from the invigorating effect of a swim in clean running water, no boy or girl should be without the accomplishment of being an average good swimmer. The need of this was never more impressed upon me than when some years ago my duty as visiting physician to the Riverside Hospital called me to North Brother Island shortly after the Slocum disaster. There I saw the bodies of hundreds of school children laid out in rows who had started only a few hours before on a happy excursion. The steamer Slocum sank at a short distance from North Brother Island. Had these little ones known how to swim a large number, perhaps all of them, might have been saved.

39. Field games, gymnastics, calisthenics, esthetic and graceful dances, and rational athletics should be taught to the boys and girls at school. These exercises will benefit the child’s physique and give it a healthy and happy frame of mind.

It is surprising how little some of our best educators think of the happiness of a pupil. The joy of living and learning, the joy of attending school, is something which must be created by alternating pleasure with work. I am firmly convinced that by a comprehensive curriculum which has the physical as well as the mental equipment of the children in view, and also their enjoyment, attendance at school will become a greater pleasure to the pupils than it has ever been before, and the additional sacrifice in taxes arising from the more complete equipment of the school will gladly be made by the parents.

40. No lesson in a public school should be longer than three quarters of an hour.

In the opinion of Herbert Spencer the average adult cannot concentrate his attention on listening to a lecturing voice for more than three quarters of an hour, we should not expect from a child a longer concentration of his attention on any subject taught during school hours. The younger the child the shorter should be the lesson. It has always seemed to me cruel to force a young child to sit absolutely still even for the space of only half an hour.

41. After each lesson of three quarters of an hour there should be one quarter of an hour’s recess for the tired pupil to rest and for the ones not tired to exercise if they please.

Even normal children are not all constituted alike; some tire more easily than others, some are in need of more physical exercise. In girls’ schools, particularly in the higher grades and in high schools, there should be special rest rooms.

42. The younger the child, the fewer should be the
home lessons; the fewer the home lessons, the better will be the work at school.

Home lessons for young children should not be given at all, and for older children they should be reduced to a minimum.

43. On excessively hot days there should be no school.

Vacation time is usually arranged to avoid holding lessons during the hottest season of the year, but occasionally there are hot spells lasting one or several days prior to or after the usual vacation. The authority to dismiss the classes should rest with the school superintendent after consultation with the school physician.

44. To have small classes and enough teachers should be the aim of every school board.

It is well known that the best results in pedagogy are obtained in small classes, that there is better control and more devotion of teacher to pupil and pupil to teacher when they have an opportunity to know each other thoroughly than is possible in a larger class. In the lower grades twenty to twenty-five pupils should be the maximum for one teacher.

45. The school curriculum should be so arranged that the mental strain shall not react unfavorably on the physical and moral constitution of the child. Lessons requiring mental strain should alternate with manual training, or work in domestic science, play, and rest.

To facilitate the change from lessons requiring much mental energy to lessons in manual labor, it is desirable that the training school should be under the same roof as the regular school, or at least very near by.

The modern motion picture films which can be made to offer such invaluable help in the teaching of natural history, geography, historical events, and also hygiene, should be one of the most important equipments of the public school. It goes without saying that only the safest apparatus should be installed, and only in fireproof buildings to avoid all possible danger from that source.

46. Unnecessary and superfluous studies or work which has no bearing on the average career of the future man or woman should be avoided. More attention should be paid to the development of character and the imparting of such general knowledge as will be actually needed in taking up life’s work.

Although the principal work of framing the child’s character must necessarily be done at home and is dependent upon heredity and environment, the school curriculum can do a great deal toward ennobling the child’s mind and freeing it from the atavistic fear which is the result of false education through innumerable generations. Fear of any kind which may manifest itself in inferiority or powerlessness, should be replaced by a feeling of strength and self reliance. It is particularly at the age of puberty that the sentiments of strength and fearless-
prehend. The genius should be encouraged but not pampered; the child who is slow should not be made to feel its seeming inferiority.

51. The trained psychologist should be one of the most important additions to any modern school. His help will be of inestimable value to teachers, parents, and pupils.

This psychologist, who should be an expert in education as well as in medicine, should be well paid so that he may be able to devote all his time to his difficult task. Many a young mind which has become unbalanced by unsuitable studies or overstudy might thus be saved. By a most careful examination of the child's mentality, in some cases even by a psychoanalysis, a serious latent mental trouble might be lastingly corrected, and above all the child's studies guided in the right direction. To the trained psychologist attached to the public school we have to look for help to decrease the diseases of the mind and nervous system so prevalent among the young a few years after school life. One of our most distinguished American authorities on nervous diseases, Dr. George W. Jacoby, of New York, in a recent paper on The Montessori Method from a Physician's Viewpoint, urges the use of the most careful psychological methods of examination, methods which alone enable us to form an opinion of value in regard to the child's mentality. He considers the Simon and Binet tests as the most reliable for the evaluation of the child's intelligence. According to Jacoby's statement, a recent writer had stated that by means of these tests the psychologist, after forty minutes' examination, can obtain a more enlightening estimate of a child's intelligence than can be reached by most teachers in a year of contact in the school room.

52. Instead of final examinations the record of the entire year should determine the promotion into higher grades. Cramming for examination is unhealthy, bad for the mind and body, and immoral.

The frequent mental breakdowns among girls and boys at examination time would be avoided by this method and in the individual pupil such characteristics as bitterness toward school authorities, jealousy, discouragement, etc., would not be developed; but efficiency, regular attendance, good behavior, and devotion to work throughout the year would be increased.

53. Boys above the age of ten would be better taught by male teachers.

I agree in this respect with my distinguished friend and colleague, Dr. J. George Adami, of Montreal. In an address delivered before the State Medical Society of New York on Certain Elementary Concepts in Education Applied to Medicine he quotes a ministerial friend who, in addressing a group of lady workers of the University Settlement, said: "And don't you get it into your heads that you are going to run this settlement, that you are going to reform these street urchins and potential hooligans by 'love'—'Love,' Bah! If you try that they will fool you every time. No! It must be by many guidance and by manly methods, even including an unhesitating knockdown blow when need arises. It's the manly man they will look up to, and by whom they will most surely be influenced. They will not 'love' him, they will worship him." We all know the hardships the women teachers have to undergo when they have to deal with boys between the ages of ten and fourteen, and very pertinently Doctor Adami says: "I freely admit—we all admit—that in those qualities which are the common property of both sexes the woman is demonstrably man's superior; but in the matter of enforcing authority on the growing youth of the male denomination she is hopelessly and helplessly behind."

54. Lessons in embryology and biology leading to the explanation of sex relation and eugenics should be taught according to the age and understanding of the pupils, and in the higher grades preferably by teachers of the same sex as the pupils.

Concerning this topic I should like to quote again from the ministerial friend of Doctor Adami. Regarding the education of the boys in this respect he says: "I hold it to be the supreme argument for design in this universe that the boy is so constituted that the greatest number of nerve endings of the greatest number of nerves find themselves in that portion of his anatomy where knowledge can most neatly and effectually be instilled and that with absolutely no harm to the rest of the economy." To this I wish to add that it is at the time of adolescence, when the boy develops into manhood and the girl into womanhood, that hereditary or acquired abnormal mental tendencies are strongest. Fortunately, it is also at this period of life that any abnormal tendencies can be most easily corrected.

55. Respect for parents, teachers, and elders, and kindness to the sick and unfortunate, to fellow pupils, and also to the animal world, should be inculcated in the minds and hearts of the young at school.

It is a well known fact that many foreign educators who visit the United States comment on the disrespect of our children for parents, teachers, and elders in general. Unfortunately, this is true in many instances and it will require the combined efforts of teachers and parents to counteract this unfortunate tendency.

56. True democracy should be taught and practiced in our schools. No secret societies should be tolerated nor snobbishness toward the less fortunate, less brilliant, or socially inferior pupil.

Recent events have shown the detrimental effects of so-called secret societies in schools. They tend to create class distinction and snobbishness. They make the poor pupil feel unhappy and inculcate in him a hatred for those seemingly better situated socially. The recent decision of some superintendents to suppress absolutely all secret societies is most laudable. The principles of liberty, equality, and fraternity should always govern the class spirit.

The wearing of appropriate uniforms for boys and girls, all made of the same material and suited to the age of the child, should be encouraged as a democratic measure. The girls to be taught to make
their own dresses. The practice in some girls' schools to have the graduation gown not exceed the price of one dollar is a good example of what can be done in this respect. One must have experienced the pangs caused to a child's heart by the difference in dress of poor and of well to do pupils in order to appreciate them.

57. History should be taught backward. This method will lead to a better understanding of the principles upon which our republic has been founded.

In a recent conversation with that distinguished pedagogue, Dr. Thomas M. Balliet, of the University of New York, I was shown the inestimable moral and intellectual value of teaching history in this way, and I am indebted to him for the inspiration to add this paragraph to my fragmentary notes. Thus, for example, the recent war with Spain, undertaken for purely humanitarian reasons, shows the highest national altruism of the age. The civil war typifies the love and compassion for an inferior race. The war of the rebellion and the French revolution, the love for freedom, etc. Thus, from each historic event can be drawn a moral lesson for the pupil and an inspiration for his future conduct as a citizen of the republic. To use Doctor Balliet's own words: "This is not really teaching history backward in the strictest sense of the word, it is, rather, reaching back one step at the time and tracing that forward as the immediate cause of a later period. The study of history in this way becomes a constant process of finding causes and explanations from conditions already known by the pupil.

"History taught forward in the usual way, beginning with ancient history, is a process of inferring probable consequences which may or may not result and which are not known by the pupil at the time but become known only as the later period is taken up. Tracing causes is more interesting as a mental process than guessing at possible or probable consequences, especially in a field as complicated as history. Then, too, if a pupil, as in the high school, must leave school before completing the course, if he has had only ancient or medieval history, he breaks off his history course at the point where he has as yet very little light on the historical problems of the present. History has been said to be 'philosophy teaching by example.' This is true only when history makes close connection with the present."

58. Civic rights and civic righteousness, political purity, and political duties, the meaning of political equality, and the obligations of the citizen toward his family, community, State, and Country should be taught in our schools, particularly in the higher grades.

The formation of clubs among boys and girls to discuss the political issues of the day should be encouraged. That it is important to make these future citizens realize the value of being familiar with all that appertains to good local and general government should be impressed upon the teachers. The boys should be induced to take antialcoholic and anticigarette smoking pledges, and the girls, under guidance of expert teachers, should form clubs for the study and discussion of the duties of woman and motherhood. In New York city the Division of Child Hygiene of the Department of Health has inaugurated "little mothers' leagues" in the girls' classes situated in the most crowded districts. The object of these leagues is to teach young girls the proper method of baby care. These lessons are of great help in reducing the morbidity and mortality among infants. The girls take better care of the little brothers and sisters entrusted to their charge, or take home the information they have received and there in turn teach their parents valuable lessons.

59. The underlying ethics of all religions, worship of God and service to man, should also be taught, but doctrinal and sectarian differences strictly avoided.

By observing this rule, many of the manifestations of hatred and prejudice among the children of different races and religions will be avoided and the moral training of the pupils strengthened. I am sure there can be no objection from parents or ministers of any religious denomination to a ten minutes' morning exercise devoted to the singing of nondenominational hymns, the exaltation of duty, and a prayer in which all children (Catholics, Protestants, and Jews) could join. To meet all possible opposition, it would be desirable to have such a service a uniform one and approved by the ministers of all denominations.

60. To attain the best intellectual, physical, and moral development of our children, we must have the best intellectually, physically, and morally trained teachers.

To this end, the teaching profession should be made attractive. Teachers should be well paid and pensions in the event of infirmity or old age should be assured to them. It is impossible to attract the best elements of a cultured class to a profession which requires so much physical strength, patience, and character; so much enthusiasm, love, and devotion, if we do not hold out to the prospective teacher the best inducements and a just reward. We must entrust to the teachers the preservation and increase of the physical welfare of the child, its mental development and general education: also the moulding of its character and the laying of the foundation of usefulness, earning capacity, and all of the moral obligations of parents of future generations. Hence the physical, intellectual, and moral make up of our teachers cannot be too high.

61. The teacher should no more be overworked than the pupil.

Too long a session or too large a class, particularly in the lower grades, is very apt ere long to make the teacher a physical wreck, anemic and neurasthenic. The toxins of fatigue which we are so anxious to avoid in the pupil we should also be eager to avoid in the teacher. Just as there should be retiring rooms for school girls, so should there be retiring rooms for teachers. They should have their study room in the school building; these
studies should have at least the comfort that is found in the private office of the average business man. Here, in the quiet of the study, the teacher could rest, and when rested do the extrasessional work of preparation and the inspection of the pupils' work. Dr. Grace N. Kimball, of Poughkeepsie, said very pertinently before the recent Congress on Hygiene and Demography in Washington, that "it is the exceptional teacher who has in her home a proper and comfortable study. Her dignity of office demands at the hands of the community a suitable place in which to work. The bedroom or the family sitting room are unsuitable; neither is the common school room suitable. After the pupils are dismissed the remaining work of the day should be completed in the environment of privacy and comfort, conducive to physical rest and mental satisfaction. This work is in the vast majority of cases at present carried home to be done in the confusion of domestic surroundings or in a cold and cheerless bedroom." In our enthusiasm for the hygiene of the pupil and the sanitation of the school room let us not forget that there is a teacher too upon whose physical and mental efficiency depends in turn the welfare of the pupil.

62. The relationship of the teacher to the principals and superintendents should be helpful.

Dr. Wm. H. Allen, of the Bureau of Municipal Research, very pertinently says in one of his recent reports that teachers should be helped, not policed, by their supervisors, and the $6,500 and $10,000 supervisors should give their time to supervision that helps children instead of devoting fifty per cent. of it to clerical work.

63. Becoming a mother should not permanently disqualify the woman teacher any more than a male teacher is disqualifyed by becoming a father.

To my mind it is unworthy of a civilized community to deprive a woman teacher of her position because she has to fulfil her highest obligations as a female citizen of a republic. Her ability to teach children and deal with them intelligently can only be enhanced by having become a mother. If the finances of the community do not permit paying the salary to a woman teacher during her absence, let her salary be withheld during that time and be given to her substitute. There are always enough unmarried teachers, waiting for the opportunity to fill vacancies. What a fearful example do we give our children, the future fathers and mothers of our country, by permitting teachers to marry, but virtually punishing them for bringing children into the world. Obviously, in the interest of both the mother and child, the leave of absence which should be granted to her should not be less than a year to fifteen months, including a number of weeks prior to the confinement.

64. The teachers should be given a voice in the government of our schools.

Whether the school is a small or a large one, there should be an advisory council composed of teachers, and they in turn should have a right to elect a delegate or delegates to represent them at the board of education. President Churchill, of the New York Board of Education, put this matter in a clear light when he said: "No problem of the board of education is more definite than that of putting and keeping a teacher in the best condition to give the best service. It is suicidal to the system to harass and irritate her with rules and requirements, to bind her with red tape. The teacher's knowledge of the school situation is first hand. In a school reduced to its simplest terms a teacher makes all the plans, adjusts all the difficulties. In a completely organized system she makes no plans, adjusts nothing. Thereby the system deprives itself of the most valuable knowledge and advice. There is no more necessary single advantage needed by a board of education than the usage of teacher cooperation, by which information and suggestion bearing on the needs of the school can be obtained."

CONCLUSIONS.

Professor R. W. Corwin, of the University of Colorado, is reported to have made the statement recently that out of twenty million school children attending the public schools, fifteen million are in bad health. Professor Thomas D. Wood, of Columbia University, his coworker on the report made at the Sixth Congress of the American School Hygiene Association, is more specific in his estimate, asserting that a careful study of statistics and the consideration of all conditions leads him to the following personal conclusions. Agreeing with Doctor Corwin on the approximate number of twenty million pupils, he says:

"From (1.5 to two per cent.) 300,000 to 400,-000 of these have organic heart disease. Probably (five per cent.) 1,000,000 at least have now, or have had, tuberculous disease of the lungs. About (five per cent.) 1,000,000 have spinal curvature, flatfoot, or some other moderate deformity serious enough to interfere to some degree with health. Over (five per cent.) 1,000,000 have defective hearing. About (twenty-five per cent.) 5,000,000 have defective vision. About (twenty-five per cent.) 5,000,000 are suffering from malnutrition, in many cases due in part at least to one or more of the other defects enumerated. Over (thirty per cent.) 6,000,000 have enlarged tonsils, adenoids, or enlarged cervical glands which need attention. Over (fifty per cent.) 10,000,000 (in some schools as high as 98 per cent.) have defective teeth which are potentially if not actually detrimental to health. Several millions of the children possess each two or more of the handicapping defects."

Perhaps this estimate is too high and it would seem to me difficult to prove the exact figures. What we know is that a very high percentage of the children attending the public schools are below par either physically or mentally. But this need not discourage us. The prognosis of disease in childhood is, as a rule, more favorable than in adult
life. The child’s mind as well as the child’s character can often be moulded and what seemed abnormal be made normal. I agree perfectly with Professor Wood when he says that the defects in the fifteen million school children are partially or completely remediable. It is my firm belief, however, that it will require not only an entirely different method from the one now in vogue in the majority of schools to deal with physical defects, but also a revolutionizing of our present educational system in general. We must have the best buildings, the best sanitation, the best hygienic supervision, school clinics—medical, surgical, and dental—wherever a large number of pupils warrants or demands the installation of such institutions, the best teachers, the smallest possible number of pupils for each class, and last but not least, the best preventive and curative measures to diminish the number of physically, mentally, and morally inferior children.

I do not stand alone in advocating the need of a thorough revolutionizing of our educational method, nor in my view on the need of rebuilding or remodeling most of our schools. Dr. George W. Jacoby, from whose paper, The Montessori Method from a Physicist’s Viewpoint, I have quoted before, says: “I lay stress upon the fact that apparent inadequacy and inferiority with the consequent incompetency are frequently due, not as is so often believed to stupidity and obstinacy but to the fact that the pedagogy which to-day is sovereign in our schools has been unable to find the key to the mental life of these children.”

One of the most brilliant women whom it has ever been my privilege to meet, a school teacher of many years’ experience and still acting as a superintendent, also an admirer of Dottore Montessori’s views regarding the encouraging of the initiative of the child in kindergarten and school, recently wrote me as follows: “It is hoped that the people in charge of the department of education may be familiarized with your motto, ‘The open air school must become the rule, the indoor school the exception.’ In a few generations, if not sooner, we shall be looked upon as barbarians because of the unnatural conditions, physical and mental, under which we conduct the system of repression which we dignify with the name of education.” I do not take quite so pessimistic a view as to think that it should take generations to bring about this betterment of conditions. I hope and pray, nay, I feel sure that it will be done and will be done soon.

The task is not so difficult as it seems, but for its accomplishment we need the united efforts of a wise government, school boards loyal to the highest ideals, well trained teachers, intelligent parents, a medical profession ever ready to cooperate with the teacher in the interest of the child, and philanthropists with and without means who are willing to devote some of their fortune to this cause, or give their personal service to the betterment of the conditions which now surround the pupils in our public schools. In his remarkable address at the opening of the Fourth International Congress on School Hygiene, Professor John Huston Finley, the former president of the College of the City of New York, now the commissioner of education of the State, has very aptly characterized this work as “the conservation of human power.” Is there anything in this world of ours more important than that? The child of to-day is the man of to-morrow; the better the physical, mental, and moral status of the child, the nearer will we approach the ideal, and men and women will become indeed the images of their Creator.

SPINA BIFIDA.

With Report of Cases.

By J. P. Hoguet, M. D.,
New York.
Adjunct Attending Surgeon, Bellevue Hospital; Assistant Surgeon, Hospital for Ruptured and Crippled.

Although this condition has been known for a long time, there is comparatively little literature on the subject. The first case reported is that by H. H. Sherwood, an American surgeon, in 1814, and from then until 1890 we find very few of them. After that, however, there has been a fairly large number, but mostly reported separately, as no one operator has had a very large number of them, on account of the comparative rarity of this condition.

The etiology of spina bifida, like that of many other congenital deformities, is not known. It has been suggested that it may be due to an intrauterine hydrocephalus, which increases the pressure within the cord, but this theory does not seem to be a tenable one. According to some biologists, spina bifida and encephalocele can be produced in some animals by feeding an excessive amount of sodium chloride to the mother during pregnancy.

In order fully to understand the pathology of spina bifida, the development of the vertebral column and the cord must be considered. The spinal cord, during fetal life, is formed by an involution of the epiblast, which makes a groove, the edges of which gradually grow together and finally unite so as to include a passage lined with epithelium. The cord is separated from the overlying skin by a gradual intrusion of mesoblastic elements, from which the vertebrae with their ligaments and muslces are formed. Each vertebra is developed from three centres of ossification, one for the body and one for each half of the neural arch. It is from a deficiency in one or both of the latter that spina bifida results.

There are four varieties to be considered: Meningocele, spina bifida occulta, syringomyelocele or myelocystocele, and myelocelo.

1. Meningocele. Here there is a defect in the posterior osseous wall of the spinal column. The skin, cord coverings, and the cord itself are unchanged, with the exception of the first named which is either very much thinned out or very much thickened. Through the cleft in the column there may be a protrusion of the dura alone, with a collection of fluid in the subdural space, or the arachnoid may be forced out with the dura, so that the fluid is in the subarachnoid space. Sometimes there may even be a deficiency of the dura, so that the hernial sac is lined with the arachnoid alone.

*Read before the Section on Surgery, New York Academy of Medicine, October 3, 1913.
the collection of fluid being in the subarachnoid space.

2. Spina bifida occulta. This is really a variety of meningocele. Here there is always a cleft in the neural arch, which may be closed with a dense fibrous tissue membrane or may give passage to a distinct meningocele which, on account of its small size, may not cause any bulging of the skin. In some cases there is a mass of fat and connective tissue overlying the cleft and possibly pressing on the cord. The only external evidence of spina bifida occulta may be a hypertrichosis.

3. Syringomyelocele or myelocystocele. In this variety there is a defect in the neural arch and in the overlying dura. The arachnoid and pia are intact, but the central canal of the cord is distended with fluid to such an extent that the posterior portion of the cord is herniated through the cleft. By reason of the distention, the posterior portion of the cord becomes very much thinned out, so that in many cases it is not recognizable.

4. Myelocoele. Here there is a deficiency in the neural arch, the coverings of the cord, the posterior portion of the cord itself, and the skin. The central canal of the cord opens directly externally and is generally represented by a raw or granulating area. This condition is obviously incompatible with life, and these children are almost always stillborn.

It will be seen from this that we have, practically, but three varieties to deal with, meningocele, syringomyelocele, and spina bifida occulta. As far as symptoms and physical signs are concerned, those of the first two varieties can be given together. In both cases the baby is born with a soft rounded tumor in the midline of the back, generally in the lumbar or lumbosacral region. The tumor may have a broad base or may be pedunculated, and pressure upon it generally causes a bulging of the fontanelles. It has been said that the skin over a true meningocele is more translucent than that over a syringomyelocele, and that in the latter variety the presence of nerve tissue always causes an umbilication in the centre of the tumor. A correct differential diagnosis cannot, however, always be made from these signs. In spina bifida occulta there is no tumor, in fact, the condition may not be discovered until adolescence. Here, according to Brincker, one of the commonest signs is the associated hypertrichosis over the cleft. There may be a scoliosis or a depression covered by scarred or wrinkled skin, or a real lipoma may be present. The x-ray in all these varieties generally shows the cleft very distinctly. Associated with these signs are the various complications, caused by an impairment of nerve elements. The most frequent of these are rectal and vesical incontinence. We may even find a prolapse of the rectum from a paralysis of the sphincter ani. Motor and sensory paralyses of the lower extremities, sometimes with deformities of the feet, are not uncommon, while trophic disturbances, such as perforating ulcers of the extremities are sometimes seen. One of the most distressing complications, which, when present, comes on early in life, is hydrocephalus, and generally means the existence of a syringomyelocele.

The defect in the vertebral column is generally in the lumbar or lumbosacral region. Moore, in 1905, collected 385 cases from the literature, and gives the following table: Thirty-four per cent. were lumbar; twenty-nine per cent. lumbosacral; twenty-three per cent. sacral; nine and one half per cent. cervical; four and one half per cent. dorsal; two per cent. occipital.

Dubreuil quotes Bellanger, who gives the following statistics out of 207 cases: Lumbar, 125; sacral, 60; lumbosacral, 49; dorsal, 25; cervical, 22; dorso-lumbar, 6; cervicodorsal, 2; and coccygeal, 2.

Both sexes are said to be equally affected. Moore, in his collected cases, found ninety-eight in males and 102 in females, but among the writer's seven cases there was only one in a female.

By far the greater majority of infants born with spina bifida die in early life. The sac may be so thin that slight pressure upon it causes ulceration of the skin, which gradually gives way, a meningitis being then set up which is speedily fatal. Some babies die shortly after birth from a rapidly progressing hydrocephalus. That there are isolated instances of spontaneous cure, is an undeniable fact, but they are very few. Here the sac slowly cicatrizes, or the skin becomes thicker, so that it forms an ample protection for the underlying cord. But if this does happen in syringomyeloceles or in meningoceles, where the sac contains nerve elements, there is an increasing destruction of this nerve tissue in the sac, with resulting permanent disabilities. In spina bifida occulta, the cord is amply protected, so that these children do not show any of the complications until adolescence. Why they occur then, is hard to say. The best reason that has been given, is that there is an unequal growth of the bones and the cord, so that tension is produced at the site of the lesion.

It would seem from this that early interference is indicated in all these cases and at present there are but two methods of treatment, injection and open resection. The former method may be very briefly mentioned, as it has been generally discard ed. It consists of the injection of a small quantity of a weak solution of iodine or some other irritating substance, directly into the sac. Obviously this is working in the dark, and this is especially so in the case of syringomyelocele, where the cord tissue itself has to be punctured and the injected fluid thrown directly into the spinal canal. In any case, if adhesions are formed in the sac, there is an ensuing destruction of the nerve elements within it, with resulting disabilities. Some fairly good results have been reported, such as those of Guibbard, who had thirteen cures out of thirty-one patients injected, and of Bellinger, who had twenty-seven cures and nine deaths. Morton, the originator of this method, announced seventy per cent. of cures, but the committee of the London Clinical Society, in their report of cases which they had traced gave the following: Thirty-five cured, twenty-seven died, four improved, and five unimproved. The method has, however, become more and more unpopular, so that now, nearly all of these cases are treated by open operation.

The operative mortality has been variously given. Moore, from his series of 385 cases, put it at twenty-seven per cent., but modifies this by say-
ing that it is thirty-five per cent. in cases operated in within the first few months of life and only five and seven tenths per cent. in cases operated in when more than five years of age. There can be no doubt that infants with spina bifida stand the operation badly, as in fact they do most surgical procedures, but there have been a number of successful cases reported. For instance, Walther successfully operated on a baby four hours old; Monod, a baby five days old; Villemin, a baby one day old; and Boyer, a baby fifteen days old. On the other hand, these same surgeons have had unsuccessful cases. Villemin operated upon a baby thirteen days old, that died. Boyer operated on three babies, all under fifteen days that died. The personal statistics of some operators have been published. They show considerable variance. Bellinger reported forty-seven cases of excision by which thirty-one patients were cured and sixteen died. Dubreuil reported thirteen cases, of which five patients died. Sachalben in 1902 reported thirty cases from the Filuklic's clinic, of which eighteen patients were operated upon. Of these, six died, twelve were locally cured, and only five completely cured. Villemin reported twenty-two patients operated upon, of whom ten died. Mayo Robson, in 1805, reported twenty operations, with a mortality of thirty per cent. Moore, in his personal cases had only one death out of seven. Broca, in 1895, after reporting several unsuccessful cases, concluded that operation was not advisable.

And yet, even though the mortality is high, an open operation is the only method of treatment we now have at our command, as without it most of the children die before adolescence. Complications which before operation seemed perfectly hopeless have been relieved by resection of the tumor and freeing of the nerve elements, as is illustrated by some of the cases of Moore, Lebrun, and the writer. Boyer, after reporting some cases, said he would operate only under the following conditions: 1. When there is no hydrocephalus. 2. When there are no paralyses. 3. When, clinically, no complications are to be expected in the sac. To the writer's mind, cases with paralyses and those where complications are expected in the sac are exactly those that should be operated in early, before the disabilities become permanent and before nerve tissue is destroyed. As for the cases complicated with hydrocephalus, the best treatment for them is still under consideration. Boyer operated upon a patient whom he cured locally, but who died two months later from hydrocephalus, and a few similar cases are mentioned in the literature. It is a question whether simultaneous tapping of the ventricles and ablation of the sac would not be the proper method of treatment in these cases.

The surgical proceeding in spina bifida is a simple one. Various methods have been devised to close the cleft. Dobroff made a bone flap from the iliac crest. Zenenko filled the defect with bone from the remains of the sacral arches and the tuberosities of the sacrum, while bone transplants from the patient and from animals have been tried. The simplest proceeding is that employed by the writer in his cases with very satisfactory results.

The tumor is incised longitudinally down to the sac which generally is dissected from the overlying skin with considerable difficulty. The dissection is continued above and below and to both sides of the sac for about an inch over the healthy tissue surrounding the cleft. The sac is then opened in the midline, in the case of a meningoele, and to the side in the case of a syringomyeloele. The spinal fluid can be allowed to escape freely as it does not seem to have any untoward effect on the patient. Careful search is then made for nerve elements in the sac. A nerve that is found to end directly in the sac wall may be cut away, as it can be taken for granted that it is functionless. The redundant portions of the sac are then excised and the edges sutured with fine catgut. The simplest method of closing the osseous defect, and that used by the writer with satisfactory results, is to make a semilunar incision, through the fascia covering the muscles on each side of the spine, about one and a half inch from the midline. The fascia is then dissected free from the muscle, leaving the broad base of the flap still adherent, turned over the cleft and sutured to the fascia of the other side with mattress sutures of chromic gut or kangaroo tendon. The subcutaneous tissue is sutured over thus, the redundant portion of the skin is cut away and the edges are united. It will be found best to put a few silk worm retention sutures in the skin as, on account of its cicatization, it generally heals badly.

The following is a brief account of the writer's cases:

Case I. G. S., aged eleven years; strong and well nourished boy; presented in the midline of the back in the lumbar region, a tumor, the size of a goose egg, covered with thickened skin, which his mother said had existed since birth (see Figs. 1 and 2). Pressure on the tumor caused no decrease in its size. The boy was active and mentally bright and showed no symptoms except a complete loss of control of the rectum and bladder. No motor or sensory loss was found of the lower extremities. Operation, May 9, 1913, at the Ruptured and Crippled Hospital, on the service of Dr. J. B. Walker, to whom the writer was indebted for the privilege of operating in the first three cases. By a longitudinal incision the skin was dissected from the underlying parietal bone. The latter was opened and two filaments of the cauda equina were found adherent to its inner surface. These were dissected free and replaced within the vertebral canal. The redundant portions of the sac were excised and the edges sutured. A flap of fascia was liberated from the right side, turned over the cleft and sutured to the fascia on the left side with mattress sutures of kangaroo tendon. The skin was sutured and a collision dressing applied. Uneventful postoperative recovery, discharged from the hospital in two weeks (see Fig. 3). He was seen July 5, 1913, when the scar was found to be strong and firm, no bulging, spine perfectly flexible. He had no control of the bladder, the urine constantly dripping from the meatus. The control of the rectum was very much improved, no involuntary discharge of fecal matter. September 25, 1913, local condition found to be as before. The control of the rectum was absolutely perfect. The control of the bladder was very much improved. Urine escaped involuntarily, but only when the bladder was very full. The stream could be started and stopped at will.

Case II. J. S., aged fourteen years; strong and well developed boy. Showed a small tumor, covered with thickened skin, with a very narrow pedicle, in the midline, low down in the lumbar region, which had existed since birth (see Fig. 4). The boy was mentally active and had no motor or sensory paralyses of the lower extremities; the control of the rectum and bladder was perfect. Opera-
tion at the Ruptured and Crippled Hospital, June 20, 1913. A longitudinal incision was made through the skin over the tumor. The sac was dissected from the skin with considerable difficulty and incised. It was found to contain no nerve elements. The redundant portion was excised, the edges were sutured, and the cleft was closed with a fascial flap from the left side, which was turned over and sutured in place on the right. The skin was closed without drainage; collodion dressing applied. Except for a temperature of 10° F. on the second day after operation, his recovery was uneventful and he left the hospital July 3d (see Fig. 5). He has been seen since and was found to be perfectly well.

Case III. M. B., aged three years. Had two brothers who were normal. Was born after an uncomplicated labor. Presently in the midline of the spine, in the lower lumbar region, a rounded irreducible tumor with a broad base covered with thickened skin (see Fig. 6). The child was not mentally bright, seemed dull and stupid, and said only the simplest words. No hydrocephalus. Loss of control of the bladder and rectum was found to be complete. Had a motor paralysis of both legs below the knees, with a double drop foot. Sensation was absent below both knees, and impaired to the middle of the thighs. Operation at the Ruptured and Crippled Hospital, July 25, 1913. The skin was opened by a longitudinal incision and the sac dissected free. On opening the latter, its walls were found to be very thick and vascular. The cauda equina could not be distinctly made out, there being no nerve elements in the sac itself, but the whole vertebral canal seemed to be filled with a mass of material which resembled granulation tissue. The operation secured that the cleft was closed with a fascial flap and the skin edges were united with interrupted sutures. Collodion dressing was applied. Recovery was uneventful and he was discharged from the hospital September 6th, at which time his wound was perfectly healed, but he had shown no improvement in the paralysis. He was seen September 26th, at which time his general condition was found to be very much improved. His mentality was better and he talked considerably more. His vesical incontinence was practically unchanged, but there was a distinct improvement in the rectal control. The sphincter ani could be seen to contract tightly, when irritated, and his mother stated that he usually had but two bowel movements a day, and at other times did not soil his clothing.

Case IV. W. W., aged sixteen days. Admitted to the pediatric service at Bellevue Hospital and transferred to the second surgical division. The writer was indebted to Dr. B. J. Lee for the privilege of operating in this case and the succeeding one. This baby was born after a normal labor and presented a round compressible tumor in the midline of the back over the lumbar region. The mother stated that this was noted at birth and that three days afterward it burst, with a discharge of pus, since when the child had had some fever. On admission he was found to be rather small and poorly nourished. The skin over the tumor was so thin that it was translucent. The mass was soft but not reducible, and pressure over it caused no bulging of the fontanelles. No paralyses were apparent. Operation September 5, 1913, at Bellevue Hospital. The sac was very easily separated from the skin in this case as no scar tissue had as yet been formed. On opening the sac, a very small quantity of spinal fluid escaped and no communication with the vertebral canal could be found, as the walls of the sac were coated with what was apparently lymph. On scraping some of this off, the communication was reestablished and the cauda equina could be very distinctly seen through the cleft. The redundant portions of the sac were excised and the edges were sutured. The cleft was closed with the fascial flap and the skin with a few interrupted sutures of silk-worm gut. The temperature which had been in the neighborhood of 103° F. before operation remained sta

tionary for a few days, and then fell to normal. The baby did very well up to the ninth day after operation, when he began to take his nourishment badly and started to lose weight rapidly. He finally died fourteen days after operation, presenting the typical picture of a marasmic baby.

Case V. P. G., aged forty-three years. Presenteda congenital tumor, the size of a walnut, over the junction of sacrum and coccyx. The skin over it was not very much elevated, and the tumor was free from any symptoms referable to it. Operation. September 24, 1913, at Bellevue Hospital. Longitudinal incision through skin which was easily separated from the sac. On opening the sac, the coccygeal canal could be seen, with a small amount of fluid. A minute communication existed through the posterior spinal ligament. The sac was excised, the posterior spinal ligament sutured and the skin closed over it. Uneventful recovery. (Although the dural opening was not sutured, the dural segment made by the sacral meningocoele does exist and is due to the nonclosure of the canal in the dural process, which is always present, running from the third sacral segment to the sacrococcygeal joint.)

Case VI. C. R., aged eleven years. Admitted to the second surgical division of Bellevue Hospital, wearing a right plaster of Paris hip spica, which had been applied in another hospital, on account of tuberculous of the knee. The preceding evening a man of the hospital staff was found over the lumbar spine in the midline. There was no tumor but the x ray showed a typical cleft in the fourth lumbar vertebra (see Fig. 7). She had a complete loss of control of the bladder, but control of the rectum was present, no major or secondary disturbances of the lower extremities. Unfortunately, operation, which was urged on account of the vesical paralysis, was refused in this case.

Case VII. L. B., aged six years. The writer's thanks are due to Dr. V. P. Gilney, for the privilege of operating in this case. This patient was a small frail looking child, with a tumor, the size of half an orange, in the midline of the back, over the last lumbar vertebra. The tumor was soft and reducible, and a distinct cleft in the vertebra could be felt through it. Its summit was a soft flexible appendage about three inches long, covered with skin. The child had a complete motor paralysis of the entire right leg which was atrophied and one half inch shorter than the left. There was an indolent ulcer on the heel of the right foot, which was not at all sensitive and which had been present for several months. Control of the rectum was good, but there was a moderate degree of vesical incontinence. Operation November 17, 1913, at the Hospital of the Good Samaritan and the Medical College Hospital. As the skin of the back was rather loose, an elliptical incision was made over the tumor, so that the appendage might be preserved as a specimen. The edges of the cleft were uncovered and the last lumbar and first sacral vertebrae found to be covered by dural sac. The dural sac was covered with an amount of fatty tissue, which was dissected off and the sac opened longitudinally. A much larger amount of spinal fluid than usual escaped, but the patient's condition remained unchanged. Two small nerve fibres were seen traversing the sac, one of which was cut away, as it was found to end directly in the sac wall. The redundant portions of the sac were cut away and the edges sutured with fine catgut. The cleft was closed in the usual way, a flap of fascia being turned on the right side of the incision, and also over the hole made in the skin of the sac. The flap was sutured to the fascia of the left side with mattress sutures of kangaroo tendon. The subcutaneous tissue and skin were sutured with interrupted sutures of fine catgut and a collodion dressing applied. The boy's temperature never rose, but he was troubled with an amount of vomiting for the first two days after operation. While he had a moderate dribbling of urine before operation, he had to be catheterized several times, as a complete resection of the urinary bladder developed and had persisted up to the date of this report (November 18th).
Judging from his own experience in the training camp method, the writer looks upon it as well nigh a specific in neurasthenia vera. These difficult cases have by its use been made very much easier to cure. Not the least satisfaction in their treatment is the feeling of confidence one has in the outcome and that it will not be indefinitely delayed. This is enhanced by the knowledge that the inept individuals will be in an excellent mental and physical condition at the end of their course of treatment, compared with their present miserable state. The name "training camp method" is applied to it because its salient features are those to be found in the training camps of professional pugilists and the like; e.g., such paraphernalia as the medicine ball, punching bag, boxing gloves; such training routine as road work, rope skipping, boxing and wrestling, swimming, steam baths and rub downs, the training camp itself being a more or less isolated cottage near the seashore or foothills, the camp and patient being in charge of a trainer. But, on the other hand, the training camp method includes the application of intensive psychotherapy, prescribed rest, diet, and suitable hydrotherapy. In short, it is a simple, common sense method of applying mental, moral, and physical hygiene. As was said, it is specific when applied to neurasthenia vera and in allied kinetic neuroses it is scarcely less so. It cannot do other than supply the normal tone to the impoverished centres—both higher and lower. It does this by relieving the patients of all responsibility or necessity for initiative at the time when they are unable to accept the former or assume the latter, thus stopping many of the leaks in their nervous mechanism. It increases their resistance and their physical and mental vigor and thereby gives them the feeling of well-being which they lack and want. In time, their feeling of awareness, as it has to do with healthfulness, becomes acute; and they lose the feelings of inadequacy and aloofness which are so characteristic of the neurasthenic and psychasthenic. The associations of the psychasthenic and hysterical become normal and any abnormal dissociations lessen progressively. Many or all of the phobias of the psychasthenic disappear entirely. The hypochondriacal symptoms are replaced by normal somatic sensations. When once they have attained a condition of normal health if family is possible for them—relapses are uncommon.

It is not the purpose of this communication to give detailed histories of all the cases treated by the training camp method. Four hitherto unpublished cases will be cited: one dementia praecox, one neurasthenia vera, one neurasthenia combined, and one combined migraine and psychasthenia. All of them belong to the severer forms of their respective diseases.

**Case I.** Miss B. A. aged twenty-five years; seen first April 7, 1910; cured in fourteen months.

Diagnosis: Dementia praecox. Subdivision: Catatonia with excitement and negativism.

Family history: A sister of her mother began to have mental disturbance at twenty-one years of age. She exhibited symptoms of melancholia with delusions; e.g., she put on mourning because of her sins. This lasted a comparatively short time. She seemed to be cured and was married at twenty-five years of age. At fifty years of age she again developed manic depressive insanity, mania

for a month followed by melancholia lasting for years and until her death. The father and his family were not all of a neurotic habit.

Previous history: As a child she was fat and healthy. After one severe attack of measles at fourteen years of age she lost weight rapidly. At nineteen years of age psychic symptoms first developed. The next year she was much shocked by seeing a friend almost meet death by drowning. Just after that she became hypersensitive and had fits of crying. At one time she had a well marked mental disturbance characterized by catatonia with repression; she would draw herself up rigidly and would not talk except in a repressed and stilted manner. This attack lasted nine months. After it she was better but has never been quite normal. In fact, she has not been natural since her first attack; she has had to be handled with great consideration by the rest of her family because of her hypersensitiveness.

Present illness: For about a week she had shown decided mental disturbance characterized by self blame and repressed mental excitement. She was placed in a sanitarium, and, unfortunately, under the care of an attendant who was a religious fanatic and possessed of very unstable emotional control. She was first seen by me at that place April 7, 1910, and was removed at once and placed in a training camp with competent attendants or trainers. The camp was a bungalow near the foothills of the Sierra where there was much fresh air. It was sufficiently removed from any neighborhood and was ideally situated for its purpose. The routine was as follows: Out of bed, 7 a.m. Salt rub (cold). Breakfast, 7:30. Walk, 8:45 a.m. Lunch, 12:30 p.m. Out of doors, 2:30. Medicine ball, gardening, walk, etc. Rub down, 4:30. Rest, one hour. Dinner, 6:30. Alcohol rub. Go to bed, 9. The medicinal treatment was as follows: Thyroid extract, two grains with muriatic acid; Blaud’s (arsenated) pills, five grains after meals. Pill of three valerianates, four times daily. For sleep, veronal, seven and one half grains at night. For excitement, fifteen grains of strontium bromide, with five grains of chloral hydrate. Every meal.

A daily history was kept in diary form for the sake of having an accurate record. This routine was rigidly adhered to with or without her cooperation. She was forced to eat plenty of good food and drank a quart of milk daily. At times she would rebel against the food. Much of the time during the first few weeks she could hardly be inveigled into conversation. She would spend hours upbraiding herself because of imaginary sins, because of watching all doors, and because of the terrible things she had done. She made several attempts to run away from the camp. She was of course watched carefully, and in May a hatpin was found secreted in her bedding. A little later she actually succeeded in leaving the institution attached to a scaffold built by her own hand with a needle she had found. Only prompt surgical intervention saved her. During July she began to have better nights and more cheerful days. Up to October she would run away the sight of a strange face. November she made a decided change for the better. During December and January it was possible to carry out more intensive psychotherapy, because she could be approached more freely. From February her progress was rapid. In May she was almost normal, and by the end of June was well. Since that time she has been more natural and has shown greater mental balance and stability than at any time since adolescence. The training was dispensed with and she was entrusted with serious responsibilities connected with an out of doors life, until she showed a remarkable ability in managing a large tract of land. This has been gradually increased and her business education carefully carried out. She has been perfectly well for nearly two years.

**Case II.** Mrs. C., aged thirty-five years. Seen first March 18, 1912. Cured in three months.

Diagnosis: Neurasthenia.

Family history: Her parents were normal and apparently healthy at the time she was first seen. The mother then her father died suddenly while abroad (heart or arterial disease) and her mother has had an attack of left sided hemiparesis that was temporary and due to arterial disturbance. A curious repetition of jaundice appearing in the family history—the patient, her sister, her daughter, and others all being jaundiced at birth.
Previous history: She was jaundiced at birth and was delicate as a child. At twelve years of age she was brought to California. A year later her menstrual history began. She suffered with dysmenorrhea from the first period until she was operated upon for relief. At twenty-three years of age she was married and has borne two children, the youngest being six and one half years old. During her last pregnancy she was very nervous and depressed. The child's speech had been delayed, and she was under the tutelage of an instructor. This arrest of development had much to do of her temperament, ceaseless anxiety and nerve rack for the mother.

Condition on admission: For the last three months she had been growing progressively more nervous and less able to respond to or assume her responsibilities. Her dominant symptoms were mental and physical fatigue, insomnia, gastric and cephalic parasthesias, mental depression. Her household matters worried her intensely, as did many things which did not do so formerly.

Physical examination: Circulation: A systolic murmur was heard over the apex. Blood pressure was 96 mm. Hg (Tycos). Pulse lacked tone. Lungs normal. Abdominal organs were normal except that the liver dulness was slightly larger than usual. Her weight was below normal and the muscles lacked tone. The skin over the hands and arms was harsh and rough (the same condition was noted in her daughter). Reflexes exaggerated. She flushed and paled irregularly, and her hands and feet were cold most of the time.

Treatment: It was deemed wise to begin her treatment with a suitable period of absolute rest. After four weeks of rest she was ready for a modified rest treatment. This consisted of the following routine. Salt glow, 7 a.m.; breakfast in bed, 7:45; resisting exercises in bed, 10; sweat and rub down, 11; rest (complete), one hour. Lunch in bed, 12:30 p.m.; sitting in chair one half hour, 2:30; resisting exercises in bed, 3; rub down; rest (complete), one hour; occupation in bed; supper, 6; alcohol rub and retire to sleep, 8:30.

Medicinal treatment: Blaud (arsenated) pill five grains three times daily. A combination of zinc valerianate, purified camphor, and extract hyoscyamus and sumbula, three times daily. Thyroid extract one grain three times daily. After this was in force a few days there were indoor exercises added to it, and, a little later, outdoor exercises. Within two weeks her routine was full training camp work, beginning with setting up exercises out of doors in gymnasium suit. This was followed at once by a salt glow and breakfast. At 9:30, road work of an hour to an hour and a half, consisting of brisk walking and running. This was varied by tennis at times. Then a rub down and rest in bed until time to prepare for lunch. In the afternoon would come a stiff round of medicine ball (see Fig. 1), rope skipping and dancing steps, games requiring speed and accuracy, a brisk walk and then a rub down and rest. On Sunday no routine work was done and the family could visit the camp or she could go on motor trips with them. Her training camp treatment lasted three months including the rest period. At its end she weighed 120½ pounds (the most she had ever weighed), her muscles were hard and supple, her endurance considerably above normal. The systolic murmur was no longer heard, and her blood pressure was 125 mm. Hg (Tycos). Her ability to sleep soundly had returned to her, her constipation was gone and she was no longer under the constant tension and feeling of foreboding. She remained in splendid health, and has been perfectly able to lead a strenuous civic and society life.

Case III. Mr. J., aged thirty-six years. Real estate. Seen first October 17, 1907; cured in less than three months.

Diagnosis: Nervasthenia and psychasthenia.

Family history: One grandfather was insane for some years before he died. Father and mother were exceptionally healthy.

Previous history: He was never robust. At eighteen years of age he had a severe attack of grippe lasting three weeks. Following this came an extended period of nervous breakdown. He came to California in order to live an all year round open air life, and in time he became quite well, for him. During later years he has engaged in a growing business requiring a constant mental strain. In addition to it, he assumed many responsibilities. The panic of 1907 determined his present condition.

Present illness: For the last few months he had become excessively nervous and irritable. This condition became progressively worse. At this time he was unable to concentrate his mind sufficiently to write a simple business communication. Any attempt to force himself to do so would cause an excess of mental distress with confusion of ideas. This naturally aroused a fear that insanity was impending. He was subject to fits of intense depression and crying. As is usual in such cases he had been told to "cheer up," "occupy the mind with other things," "don't worry," and the like futile advice. His initiative was gone, and he was possessed by fear in consequence. He suffered with insomnia. He worried about everything imaginable. He even worried because his appetite was good and his bowels were regular.

Physical examination: His muscles were flabby and his reflexes were overactive. Otherwise his physical condition was good. The urine was normal.

Treatment: A suitable routine was laid down for him to try at his home. He adhered to it faithfully and with fairly good results for a time. He was then prevailed upon to try the training camp method. A suitable cottage on the edge of the ocean was chosen and fitted up for the purpose in view (see Fig. 2). The patient and camp were placed in charge of a professional trainer of pugilists and athletes (the latter, of course, took all orders from the

Fig. 1.—Playing medicine ball (Case II).

Fig. 2.—The training camp (Case III).
cine ball, boxing, and wrestling, 2:30 to 3:30; rub down; rest in bed one hour; supper, 6; go to bed, 9. At first there was a good deal of muscular soreness and disagreeable paresthesia of various kinds. But he stuck to it faithfully. After six weeks he was in good condition. The psychasthenia became less, but there was no more fear. He felt adequate to meet normal responsibilities. He was advised to round out his treatment by a trip to his parents' home in the East. When he returned he took up his car again and was vigorous and satisfied. In the last four and a half years he has been in perfect health.

CONCLUSIONS.

Inasmuch as we believe that the functional or kinetic neuroses are characterized by pathological exhibitions of the functions, therefore the rational treatment of them must be a problem of kinetics, anthropology, and psychology.

The training camp method of treatment makes use of the well known rest treatment of Mitchell in suitable cases. It invariably makes use of intensive psychotherapy. It systematizes and prescribes the amount of rest, diet, and exercises. During the period of treatment—at times from the very beginning—the training consists of the more or less strenuous régime that has been used by athletic trainers for the purpose of enhancing mental and physical vigor, but in such amounts as shall be suitable to the individual in hand.

The training camp method is not put forward as a cureall; it is only a rational adaptation of well known curative measures. The method is based upon a series of thirty cases of neurasthenia and psychasthenia, eight cases of dementia precox, two cases of hysteria, and two cases of alcoholism.

AUIDITORIUM BUILDING.

INTESTINAL OBSTRUCTION DUE TO A BENIGN PELVIC TUMOR.*

Report of a Case.

By ROBERT M. ALEXANDER, M.D.,
Wernersville, Pa.,
First Assistant Physician, State Asylum for Chronic Insane.

Case. F. H., female, aged fifty years, had been in institutional care since 1899. Was admitted to Wernersville State Asylum for Chronic Insane in 1899. Patient at that time was in good physical condition and abdominal visera were reported normal. There had been no record of physical ailment during her residence here. She frequently complained of her clothing being too tight about the waist, but this was considered a delusion.

Physical examination showed patient to be a fairly well nourished adult female. Pupils were equal and reacted to light and accommodation; the tongue was clear, slightly

*Read before Berks County Medical Society, November 11, 1913.
tremulous, protruded in the median line; teeth were fairly good, a few missing; pharynx and tonsils appeared normal; thyroid gland was slightly enlarged; the chest appeared normal, expansion was equal on the two sides and no areas showing pathological change were demonstrable; heart sounds were rapid but of good quality; no murmurs heard.

Abdomen. A bulging mass occupied the lower, left hand quadrant. Tenderness was marked, slight rigidity present. Pelvic examination showed it to be connected with the uterus. It was hard, nodular, and movable. The patient's bowels at this time had not moved for two days. She was seized at that time with severe abdominal pains and persistent vomiting, but no fecal vomiting occurred. On the third day of attack a very small amount of feces was expelled, at the same time the tumor was seen to have increased greatly in size and the symptoms had increased in severity.

The abdomen was opened, and the parietal peritoneum was injected. Upon incising this, a large congested tumor came into view. This, it was found, had caused the uterus to be twisted upon itself and upon its appendages twice. It was untwisted, when it was found that a coil of the transverse colon adhered to the fundus of the uterus at its posterolateral aspect. This was pushed off with gauze. A quantity of serosanguineous fluid was found in the pelvis. Pelvisyndectomy was performed. There was no drainage following operation. Patient presented an intermittent temperature for several days. Recovery was otherwise uneventful.

PATHOLOGICAL FINDINGS.

The urine report was negative.

The right ovary appeared normal.

The left ovary was enlarged and congested; microscopically it showed hemorrhage.

The uterus was greatly enlarged and congested and microscopically showed the presence of hemorrhage.

The dimensions of the tumor were, breadth 17.5 cm., length 10 cm., thickness 10 cm. Microscopical examination showed it to be a fibroma. The pedicle of the tumor was 5 cm. long. It weighed 120 grammes.

MEDICAL SOCIOLOGY IN THE PUBLIC SCHOOLS.

By Mary Sutton Macy, M.D.,
New York,
Assistant Neurologist, Brooklyn Dispensary.

The school child presents a number of medical problems, some of which are entirely understood, some are in the experimental stage, and some are absolutely unappreciated as such by physicians or teachers.

In the brief space at my disposal I shall touch but lightly on a number of aspects of one of these problems, i.e., the laggard. From the physician's point of view the laggard is a problem either in faulty hygiene or in pathology. From the teacher's point of view the laggard is a drag on a class, a blot on the fair reputation of the teacher, or a problem in discipline, or all three. From the social point of view the laggard is an increased expense, a social menace, or a problem in social adjustment.

From all these points of view the laggard is a desirable thing to eliminate or to mitigate as far as possible. Prevention is obviously the ideal, but unfortunately, for this condition, prevention necessitates removal of cause, and the causes for laggards in the schools are legion. To summarize them briefly we recognize: 1. Retardation from prolonged or frequent absences, whether due to frequent illness, frequent change of home locality or school, or both; parental negligence or indifference; truancy per se; or other causes of irregularity in school attendance; 2, retardation from physical inefficiencies or deficiencies, which may cover not only such conditions as blindness, partial or complete; deafness, partial or complete; adenoid vegetations and similar much discussed physical defects; but also tuberculosis, anemia, infantile paralysis, and cerebrospinal meningitis, with their sequelae, etc.; 3, retardation from mental inefficiency or deficiency, under which heading must be grouped not only the imbeciles, idiots, cretins, and morons who are outside State or municipal institutions for the segregation and care of such cases, but also that much larger and more important group of so called "borderline cases," which, from malnutrition or physical inefficiencies, or both, have been so far retarded as to make differentiation on first or even second examination almost impossible. Elsewhere I have presented this later case rather more in detail.

With these problems of retardation—veritable medicosociological problems—confronting the school authorities, what is to be done? What has been done?

Medical inspection, as conducted here in New York city schools, under the Child Hygiene Bureau of the Department of Health, has done most excellent work in controlling contagious diseases and in promoting various phases of child hygiene. Numerically speaking, the problem is tremendous and the department of health force admittedly too small to accomplish even the routine inspection, once a year, of every child in the public schools.

It depends largely upon the personality of the inspector, however, as to the relative amounts of pure inspection and of medical inspection plus medical sociology that is done in this work. I know the old defense "lack of cooperation," but I have noticed, too, that where the medical inspector takes a personal interest in doing more than merely inspect, cooperation is never lacking. The principals and teachers who face the same problems with a given child day after day, until they are literally "worn to a frazzle," are all too eager to grasp any opportunity of relief suggested, but they cannot reasonably be expected to think out all avenues of medical relief for themselves.

There are a number of fields, however, which the routine medical inspection does not cover—though occasionally and semioccasionally it may touch them. One of these, the hygiene of the teacher, is of considerable importance to the child. For example, a sick teacher—man or woman, struggling against disability, because financial pressure and economic questions of the home or family demand

The sacrifice and the struggle—can demoralize not only a class of forty to sixty children, but the whole school, through the reflex influence exerted on the personnel of the staff. Another of these uncovered—though not untouched—fields is the hygienic construction and care of the school buildings, and of the annexes to schools in congested quarters of the city. Still others are such old time familiar slogans as the partially deaf, the partially blind, the untrained, the faults of posture, the over-crowded curriculum, etc., etc., with the solution and mitigation of which the medical fraternity has had too little to do directly. Some, if not all, of these fields offer vast opportunity for good work under the new administration of Doctor Crampton’s department of educational hygiene, though I am not presuming to suggest that these few by any means cover the opportunities at the command of this new department, and perhaps all of these do not fall within its province.

The psychomedical problems of the laggard are tremendous. We cannot have physical deficiencies without some corresponding mental inefficiency, except under most unusual circumstances, such as Helen Keller for instance. Therefore we need—and we have—in our school system classes for the blind, for the deaf, for the crippled, for the anemic, for those suffering from trachoma, from tuberculosis, and for the mentally defective. We have no classes as such for the epileptic, and into the so-called ungraded classes for the mentally defective we are forced to put morons and idiots, cretins and imbeciles, some epileptics, and a very, very large number of borderline cases. There are coaching classes for foreigners who speak no English, for laggards because of unavoidable and brief absences, that they may regain their grades, and for coaching children who appear capable of jumping a grade, and classes exist for truants, temporary or habitual, but all of these special classes are too large, or in other ways unsuitable for the borderline case. The psychomedical work of differentiating these children falls on the Department of Ungraded Classes, and primarily upon Doctor Smart, who for seven years has been the only physician attached to that department, and Doctor Krause, who has recently been appointed as an additional physician. This gigantic problem needs and deserves the active cooperation of the medical profession and some solution to the present difficulty arising from grouping real institutional types of feeblemindedness with the borderline group. Most unusual and most telling for good has been Doctor Smart’s work in sending children to special dispensaries, to convalescent homes, to hospitals, and to private physicians for innumerable necessary treatments, or for prolonged care in the country, with nourishing food, etc., etc., to rebuild an undernourished laggard not always in need of the specialized pedagogy of the ungraded class. Arrangements should be made for more physicians in clinics, or out of them, to cooperate actively with this department, by receiving the cases and reporting back to Doctor Smart or Doctor Krause the necessary treatments which have been instituted, the condition found by the clinical examination, and by bacteriological and other examinations made in cooperation and so offering a reciprocal field for cooperation for “the good of the child.” Most physicians fail to appreciate or understand that active cooperation may be obtained from the children’s teachers, if a few pertinent suggestions can be made to them. It is not always necessary for the clinician to take time to see the teacher, if he or she will take pains to report back the cases, as I have suggested. Doctor Smart and Doctor Krause are in touch with the teachers and can make the necessary suggestions, with the added force of “official position” in the schools.

No sketch of the medical sociological work of the schools would be even semicomplete which failed to mention the school lunches. These are experimental only in certain of the public schools, though the Children’s Aid Schools (the so-called Soup Schools) have had them for some time past. One interesting phase of the experimentation is the attempt to provide nourishing noonday meals which shall not conflict with the religious or the racial prejudices of Jewish, Italian, Irish, German, or other nationalities represented in our polyglot school population. This phase of the work is entitled to the active interest and cooperation of the medical profession and is fully as important in its field as the milk stations in theirs.

All physicians, and especially all pediatricians, should be familiar with the pioneer work for the blind children of the late Miss Bingham, Inspector of Classes for the Blind, and the Influence of the Elementary and Trade School for the Deaf on East Twenty-third Street. The motive ideal in both cases being to take children who are physically handicapped, and by a special degree of specialized training, combined with the general training of the normal child, to produce a citizen capable of competition with normal people on an equal footing. I cannot give the exact figures of the blind children at present in the regular classes of our public high schools who, having been trained under Miss Bingham’s early supervision, are progressing as normal students and “making good,” but the number is large. The work for the deaf, inaugurated in the city by the late Miss Margaret Regan and now carried forward in the school she organized by the present principal, Miss Carrie Kearns, turns out children who, because of their lip reading and their speaking ability, are essentially normal. This work deserves the active and intelligent cooperation of the medical profession. In fact, these ungraded classes, these blind classes, these deaf classes, these cripple classes, and the like in the public schools organized, systematized, and brought up to a high level by lay workers, with the advice and cooperation of only the occasional and exceptional physicians, put rather a black mark against our highly esteemed professional dignity. Why are we, especially the pediatricians, so busy with private interests and hospital problems, that we have neglected—and, more shame to us, continue to neglect—the opportunity of being pioneers and active promoters of this genuinely medical sociological work of the public schools.

Classes exist, as I have stated, for blind, deaf, crippled, anemic, tuberculous, mentally defective, and children suffering from trachoma; medical co-
operation—which shall consist in constructive not destructive criticism, enlarged clinical facilities with return reports to the school people—can help to untangle the present difficulties of congestion in the ungraded classes; medical cooperation can assist in demonstrating the need for epileptic classes and in educating the public to accept and to value them; medical cooperation can assist in demonstrating the value of vocational work for normal children according to physiological age laws rather than chronological age laws; and medical cooperation can make much more effective and much easier the excellent work already being done by some of the physicians of the board of health, by Doctor Crampton's Department of Educational Hygiene, and by Doctor Smart and Doctor Krause, of the Department of Ungraded Classes. “Where there's a will there's a way!” I ask, “Have you the will?”

101 West Eightieth Street.

AN EPIDEMIC OF TRICHINOSIS IN PENNSYLVANIA.*

By John Ballagi, M. D.,
Homestead, Pa.,
Pathologist to Homestead Hospital.

Ch. Simon, of Baltimore, in the introduction to the second edition of his Infection and Immunity, just published, says: “Cholera, plague, typhus fever, typhoid fever, yellow fever, smallpox, malaria, and diphtheria are diseases which, if they still exist among civilized people, do so with the consent of the people in the face of a full knowledge of the manner of their prevention.”

Simon is right without doubt. Still, if we are taken sick with typhoid, or malaria, or yellow fever and so on, we might be excused: individual and public too. One has to drink a glass of water or milk once in a while and has no means to sterilize it first. Or, one may get bitten by a mosquito or bedbug, not knowing it to be a carrier. And as to general, public prevention, to guard a whole population against typhoid, malaria, diphtheria, etc., costs a great deal of money, time, work, and brains.

But that is not the case with trichinosis; it is very easily preventable. Therefore no public authority which permits trichina infected meat to be sold deserves pardon; neither does the individual who has the bad taste to eat raw pork.

We have two easy, inexpensive ways to prevent trichinosis. The first, as I pointed out above, belongs to the sphere of public hygiene; systematic meat inspection, as practised in Germany. Since Germany introduced compulsory meat inspection for trichine, neither epidemics have occurred there nor single cases. They solved the question with real German thoroughness: no hog may be killed, or meat imported or sold without first being inspected for trichine.

The second method is a matter of personal hygiene and very simple too; do not eat any pork raw or which is not roasted or well cooked. Keep away from smoked ham and sausages, potted ham or canned food, when they contain hog's meat and are not cooked. The only exception is bacon, which never contains trichine.

The diagnosis of trichinosis is difficult in single cases, easy in epidemics. At all events we may expect some help from considering the religious rules and racial habits of the patients. We know that trichinosis is almost impossible among orthodox Jews, Turks and Hindus since they never eat pork. On the other hand, Germans are more exposed than other nations, because they consume a great deal of pork uncooked, in form of raw ham, raw or smoked sausages and so on. Osler lays particular stress on this point in his Practice of Medicine, fifth edition, p. 354, saying: "Trichinosis should always be suspected when a large birthday party or Festa among Germans is followed by cases of apparent typhoid fever." All the great epidemics have occurred in Germany. There is only one greater epidemic recorded outside of Germany; it took place in Hungary, in the year 1861, and was reported by me in the Hungarian Medical Weekly, the same year. Hungarians eat only well cooked or roasted meat, so this epidemic was somewhat of a surprise until more particular data could be obtained. That is to say, out of nearly 100 persons, who ate of the same shipment of sausages, fifty-one—all Germans or Bohemians—became infected, the rest—Hungarians—escaped.

Since hogs raised in this country are not free from trichine (on an average fifteen per cent. of the killed swine showed trichine, according to Reddig's and Marke's investigations in Boston), it is not to be wondered at when cases of trichinosis occur in the United States, not with alarming frequency, true, but often enough. Doctor Blackburn, of Philadelphia, in the July, 1913, number of the Pennsylvania Medical Journal estimates the number of all cases reported from the United States at about one thousand. Owing to the difficulty of recognizing isolated, mild cases, there cannot be any doubt that the cases not reported are far in excess of the number given. The mortality is fluctuating and depends on many circumstances, but it averages about twenty per cent.

In Pennsylvania, last year only, Doctor Merkur, of Pittsburgh, reported one case observed by him in the South Side Hospital, finding the trichine in the circulating blood. As he privately informed me, several cases occurred among Italian laborers in Beaver Falls, Pa., the same year. Doctor Blackburn, as mentioned above, reported one case from Philadelphia. Reading his paper, one can hardly have any doubt that his patient really had trichine: the clinical symptoms are convincing enough. Still it is to be regretted he did not demonstrate the trichine, but made the diagnosis solely from the clinical symptoms and from the eosinophilia.

The Journal of the American Medical Association cites four reports of trichinosis cases observed in 1912, two from California, one from Ohio, and one from New York.

The epidemic I am reporting here occurred in Daisytown, Washington county, Pennsylvania, in August and September, 1912. Daisytown is a small mining settlement inhabited by foreign miners, mostly by Slovaks, Poles, Italians, and Hungarians. There were six cases I saw and about twenty more attended to by the coal company's local physician.
or other doctors in the neighboring towns, or by nobody at all, some of the patients exhibiting very mild symptoms only.

I did not see the six patients all the same time; they came to my office in Homestead separately, with a few days interval between. So it happened that the first two cases were dismissed with a wrong diagnosis; one as gastrointestinal catarrh, the other, there being facial edema, as a probable nephritis. However, when a third patient came from the same place, with a slight rise in temperature, muscular soreness, etc., I became suspicious, sent him to the hospital, and made a blood count. Finding sixty per cent. eosinophiles, I examined the blood of the first two and the subsequent four patients who came two days later from the same place. Result as follows:

<table>
<thead>
<tr>
<th>Patient</th>
<th>Leucocytes</th>
<th>Eosinophiles</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. L.</td>
<td>12,000</td>
<td>70 per cent.</td>
</tr>
<tr>
<td>2. J. B.</td>
<td>12,000</td>
<td>58 per cent.</td>
</tr>
<tr>
<td>3. M.</td>
<td>10,000</td>
<td>51 per cent.</td>
</tr>
<tr>
<td>4. B. V. J.</td>
<td>10,000</td>
<td>45 per cent.</td>
</tr>
<tr>
<td>5. R.</td>
<td>11,000</td>
<td>40 per cent.</td>
</tr>
<tr>
<td>6. S.</td>
<td>9,000</td>
<td>30 per cent.</td>
</tr>
</tbody>
</table>

The high proportion of eosinophiles is remarkable—between thirty and seventy per cent. or eighty in one hundred, being the highest ever found.

There was nothing else but to find the trichine. I am sorry that at that time I had no knowledge of the fact that trichine can be demonstrated in the circulating blood as Herrick and Janeway had shown in 1906 (Archives for Internal Medicine). Doctor Merkur was so kind as to make me acquainted with that simple method of finding trichine in the human body. The Herrick-Janeway procedure has the advantage over the excision of pieces of muscle, that it can be performed very easily; people usually object to excision. Luckily one of my patients gave his consent to the operation and Doctor Campbell excised a small piece of the left biceps, near the lower tendon. Lacerated or cut and stained preparations showed many trichine, partly rolled up already or still straight, all without a capsule, but surrounded by a mass of leucocytes.

Regarding the source of infection I learned the following: All the patients were adults, males, miners, of Hungarian nationality. Pork is a staple food with Hungarians, but as mentioned above they do not eat it raw. These patients denied eating raw meat too. Close questioning, however, elicited a simple explanation, namely, that the epidemic was caused by consuming insufficiently roasted meat. All the patients lived in two boarding houses, the meat was furnished by the company store in big “chunks” of twelve to fifteen pounds or larger, roasted in an open pan on the top of the cooking stove, and cut up afterward. Sufficient, thorough cooking in such a way is hardly possible. Considering the fact that trichinous meat needs a temperature of 75° to 80° C. for six to seven hours to kill encapsulated trichine, infection by only apparently roasted meat may easily take place.

The patients all recovered after an illness of varying from three to six weeks. Two of them, whom I had the opportunity to see four months afterward, were still complaining of muscular soreness and general weakness.

I have to thank Doctor Maclachlan, Doctor Prodey, and Doctor Campbell for their help.

Abstracts and Reviews.

THE NERVOUS SYSTEM; ITS ORIGIN AND EVOLUTION.*

By Professor G. H. Parker,

Boston,

Harvard University.

Personality, or rather those several attributes which go to make up personality, such as love, hatred, fear, and the like, were believed by the ancients to reside in the several different viscera—liver, spleen, heart, etc. The nervous system and brain were thought to have little function. Although some of these ancient beliefs persist in many of our common forms of speech, we now recognize the nervous system as the seat of all of the attributes of personality, in addition to being the general controlling mechanism for nearly every known act or function. It was, however, only about twenty years ago that Waldeyer first enunciated the belief that each nerve cell, together with its processes, was a unit anatomically and, to a certain extent, functionally. The neuron became the ultimate unit in the central nervous system, which was then recognized as an intricate collection of these anatomically and functionally different cells.

Following the recognition of the unity of the neuron came the segregation of these units into functional groups. Of the three groups, two lie partly within and partly without the central nervous system—the sensory and the motor neurons. The third group lies wholly within the central system—the association neurons—the cell processes running up and down between different regions within the central structure. These latter neurons are vastly the most abundant of all in the higher animals, and are found to diminish in abundance as we descend the scale of animal life, until they finally disappear.

The functional division of these three neurons differs materially from their exact anatomical division. The sensory and other specially differentiated endings make up the receptor mechanism. Muscle, gland, and other cells not strictly nervous form the effector mechanism. All the nervous structures lying between these two constitute the adjustor mechanism. This latter includes the entire sensory neuron except its ending, the whole association neuron, and the motor neuron, or its counterpart for gland and other structures.

The nervous system of the higher animals consists, therefore, of a most intricate mechanism for the reception of impulses, their conduction and distribution, and the production of a response to stimulus. It is a reflex mechanism in the broader sense of the word.

The reflexes may be divided into conscious and unconscious. The former are typified by the reaction of the iris to light: the latter by the muscular response to a painful stimulus. The question of personality in the lower animals resolves itself into the determination of the proportion of the conscious reflexes to the unconscious. The origin and

*Abstract of a lecture delivered before the Harvey Society, Academy of Medicine, New York, November 20, 1913.
The evolution of the nervous system are to be sought by a study of the nervous structures and mechanisms in the lower forms of animal life.

Descending the scale to the earthworm, we find that this animal contains a relatively small number of association neurons and is essentially a creature responding to stimuli through the mechanism of the unconscious reflex. In spite of its extremely rudimentary brain analogue, and its great lack of association neurons, experiments seem to show that this animal can profit by experience—can learn. Such an ability to profit by experience, though extremely slight and sluggish in response, is somewhat comparable to intelligence. It must not be concluded, however, that the lower animals actually perform many acts consciously, for even the bee in the building of its comb is acting by virtue of an innate mechanism, purely of an unconscious reflex nature, and not as a result of having learned by experience of contact with its fellows in the hive.

We must conclude that the lower animals are mainly machinellike, acting almost exclusively in response to unconscious reflexes, and that they have very little which is comparable to consciousness.

Lower in the animal scale stands the ctenophora, which is little more than a digestive sac. In these animals we find no trace of a centralized nervous system, and association fibres are wholly wanting. There are merely sensory and motor neurons in direct relation to one another. Their actions are purely unconscious reflexes, and each portion of the animal contains its own neuromuscular system, which is capable of coordinate response after complete separation from the rest of the body. The adjustor mechanism is absent, and, as this is the essential feature of the central nervous system, we are led to the conclusion that the central nervous system is the last to develop in the animal kingdom.

Two hypotheses have been advanced to account for the development of the sensory and motor neurons. The first is that both arose originally from a single ectodermal cell, in which developed sensory functions on its surface portion and contractile powers in its deeper parts. This cell ultimately became divided into two cells, each retaining but one of the functions. The second view postulates the simultaneous differentiation of two ectodermal cells, the one into a sensory cell, the other into a contractile structure. As the result of work on certain sponges, I am led to take issue against both of these views.

About the pores of these sponges muscle cells are found, which are capable of closing the pores. These cells contract in response to stimulation, but do so very slowly. Transmission of impulse does not exceed half a cm., and is extremely slow, taking place directly through the protoplasm, like the transmission between the cells of ciliated epithelium. In these animals there is no trace of nervous structure, and I am led from these observations to the belief that the effector system preceded the nervous system in the course of evolution, instead of there having been a simultaneous development. Certain confirmation of this hypothesis is found in the fact that even in higher animals muscle is known to react in the absence of nerve influence. Thus the iris will contract to light when it contains no living nerve structure, the embryonic heart contracts before nerve cells have developed, and Carrel has seen recently developed, isolated cells of the artificially cultivated chick's heart contracting rhythmically.

My belief is that muscle is the primitive tissue, and that the receptor nerve mechanism is a later development around this effector mechanism. "We have brains because we have receptors, and we have receptors because we have effectors."

These explanations have dealt with the sensory and muscular neurons exclusively. How are they to be applied to the control of other effector organs such as the glands, chromatophores, electric and luminous organs? These structures are controlled by nerves in some cases and to a certain extent, and in others by chemical agents. For example, the major functions of the human pancreas are not under direct nervous control, but are stimulated and inhibited by the intervention of hormones. Where nerve control is present, however, it seems plausible to believe that the nerve structures have gradually appropriated the control, the analogues of motor fibres gaining ascendancy over glandular and other effector structures. Similarly, there has also been considerable appropriation in the course of development on the part of the sensory nerves.

There are three types of sensory neuron structure. The primitive one is that in which the sensory neuron cell body lies in the surface epithelium; exemplified in higher animals by the olfactory nerve. A further development occurs with the migration of the cell body inward from the surface, leaving the nerve ending as the receptor mechanism; represented by the simple nerve endings which are stimulated in response to common chemicals, as acids, alkalies, etc. Last, there is the development of specialized epithelial cells as receptors for the nerve cells; typified in the taste buds.

The acuity of response of these three types of sensory endings corresponds to a certain extent, to their development. The first form is the most acute, the second is the most obtuse, and the last developed is intermediate in sensitiveness. The truth of these statements may be demonstrated in man by the testing of the three functions with a single substance which possesses taste, odor, and the power of evoking common chemical sensation. This is ethyl alcohol. The acuity of the olfactory type of endings is such that the odor of alcohol can be detected in a one eight thousandth molecular dilution of the substance in air. The simple nerve ending is so obtuse that a five molecular dilution is required to give the common chemical response—that is, a solution forty thousand times as strong. Taste is evoked by a three molecular solution, or one twenty-four thousand times as concentrated as is required for the stimulation of the olfactory nerve cells.

Such are the facts and hypotheses which we have been able to deduce regarding the origin and evolution of the nervous system, and I may conclude by saying that the nervous system has grown up as a set of triggers to set off the effector mecha-
anisms; that there has been a gradual appropriation by both the sensory and motor neurons; and that last, there has been the development of association neurons with a welding of the whole into a complex and intricate system which constitutes the central nervous system of the higher animals. The higher we rise, the more complex is the system, and the more abundant are the association neurons.

Prize Essays.

Questions for discussion in this department are announced at frequent intervals. So far as they have been decided upon, the further questions are as follows:

CXL._How do you treat the symptoms of senility, without organic disease, but showing approaching dissolution? (Answ. due not later than November 15th.)

CXL._How do you treat frostbite? (Answ. due not later than December 15th.)

CXLIII._How do you treat chronic constipation? (Answ. due not later than January 15, 1914.)

CXLIII._How do you treat gallstone colic? (Answ. due not later than February 16, 1914.)

Whoever answers one of these questions in the manner most satisfactory to the editor and his advisers will receive a prize of $25. No importance whatever will be attached to literary style, but the award will be based solely on the value of the substance of the answer. It is requested (but not required) that the answers be short, if practicable no one answer to contain more than six hundred words; and our friends are urged to write on one side of the paper only.

All persons will be entitled to compete for the prize whether subscribers or not. This prize will not be awarded to any one person more than once within one year. Every answer must be accompanied by the writer's full name and address, both of which must be at liberty to publish. All papers contributed become the property of the Journal. Our readers are asked to suggest topics for discussion.

The Prize of $25 for the best essay submitted in answer to Question CXXXIX was awarded to Dr. J. Walker Moore, of Philadelphia, Pa., whose article appeared on page 1117.

PRIZE QUESTION NO. CXXXIX.

TREATMENT OF CHANCROID.

(Continued from page 1121.)

Dr. R. W. Reynolds, of Lincoln, Nebraska, finds:

In conducting the treatment of chancroid, several things must be taken into consideration, for example, the site and number of ulcers, age of lesions, and the habits and general surroundings of the patient. To explain more fully and exemplify we will take up the points in the order named. First, site of lesions: If the ulcers were located at the urinary meatus or within the urethra, the cauterization treatment would be contraindicated, on account of the great danger of stricture or other deformity. Second, the age of the lesions: The cauterization treatment, so frequently and effectively used, does not promise so much for speedy and sure results, if the ulcers are more than four or five days' standing. Third, the habits and general surroundings of the patient: Every physician has some patients who are uncleanly and careless about their own care as well as the possibility of spreading infection to others, and others, yet, who, no matter how much they are disposed to be cleanly, are so situated that it is next to impossible for them to give themselves proper care and treatment. In cases of the latter type, it is obvious that the shortest and quickest treatment is the best treatment.

The treatment itself may be divided for sake of description as follows: Abortive treatment, palliative treatment, and treatment of the complications.

The abortive treatment. The object of this treat-

ment is to convert virulent chancroidal ulcers into healthy granulating sores. This treatment, if used at all, should be used early, as it does not promise so much if used later than three to five days. In order to transform a chancroid into healthy granulations, powerful agents are required, such as the actual cautery, fuming nitric acid and carbolic acid. These are the favorite and best known in this con-

nection. The lesions should be prepared for cauterization in the following manner: Cleanse each ulcer with hydrogen dioxide and make as dry as possible with sterile gauze. When this has been accomplished, powdered cocaine or beta eucaine is sprinkled directly on the raw surface. This is left in contact for a minute or two and is then removed with plain sterile water. The parts are now dried and the actual cautery, which has previously been heated to a white heat, is applied to the entire sur-

face for a short time, care being taken to cover every nook and crevice. A wet dressing should now be applied, of gauze saturated with either bi-

chloride of mercury solution one in 3,000 or lotio nigra, which may be protected from evaporation by the use of oil silk or rubber tissue.

If the actual cautery is not at hand or for any reason is not used, then the following procedure, which is the one I most frequently use, may be carried out. Cleanse and anesthetize as above and around each lesion to be treated, apply with a wooden applicator, a thin coating of petrolatum, dry the ulcers with small pieces of absorbent paper and apply with a glass rod having a sharp point fuming nitric acid thoroughly, and allow this to remain until cauterization is complete, which usually requires two or three minutes. Moisture is now removed with absorbent paper and a dusting powder or a wet dressing of bichloride of mercury (one in 3,000) or lotio nigra is applied. I think wet dress-

ing is preferable on account of the well known ten-
dency of powders to crust and thus form a pro-
tection for the infection. This treatment will prove effective if applied early and most patients will be well in from ten to fourteen days. If applied later than three or four days after the beginning of the trouble, it may be necessary to repeat the cauterization treatment a second or third time, and each time follow with the antiseptic treatment as in the first instance.

Palliative or expectant treatment. This treatment will prove successful in most cases in private prac-
tice, where the conditions are more favorable and where the patients can and will give themselves the attention needed or when the more speedy cauterization treatment is refused. It is carried out about as follows: Cleanse the parts as well as possible with hydrogen dioxide solution twice each day and apply a wet dressing on gauze of bichloride of mercury (one in 2,000 or one in 4,000) or lotio nigra. If the ulcers are situated beneath the foreskin the
dressing may be applied by cutting out a piece of gauze about four inches square and folding the same once on itself and cutting a notch with shears at a point which will be near the centre of the square when unfolded. The hole should be cut rather small, as it can be stretched to the required size, which is just large enough to slip comfortably over the glans penis and into the corona sulci. The gauze square is gathered into a wad to facilitate wetting with the solution to be used, the excess is squeezed out and the square straightened and slipped into place after the prepuce has been retracted, the four tails are pulled down over the glans and the prepuce is replaced in its normal position. With a dressing applied in this way, the prepuce serves as a retainer for the dressing. A dressing of this kind serves a double purpose, that of a vehicle for the antiseptic solution as well as keeping the infected tissues separated from the healthy ones. Occasionally the cure is facilitated by the use of silver nitrate solution or pure lunar caustic in a stick. This should only be applied around the edges of the ulcers for the purpose of stimulating granulations and should not be used until the infection has been conquered. This remedy is used by some as a caustic, but it is not effective, as it simply coagulates albumen and does not penetrate deep enough into the tissue. Powders will at times prove efficient as stimulants to the healing process and thymol oxide, bismuth formic iodide, europhen, and last but not least iodoform, have all served in this capacity. Iodoform is most effective, but there is always the objection to its odor. Ointments as a broad rule should not be used in the treatment of chancreoids. I have found, however, the following ointment recommended by Lydston of use in some cases, for the purpose of stimulating granulations.

B. Iodoformi, ................................ 3½; Balsami peruviani, .............................. 3½; Adipis lanze hydrosi, ................. 3½.
M. Sig.: Apply on lint or gauze.

I have used the following also suggested by Lydston for the same purpose:

B. Iodoformi, ............................. 3½; Etheris sulphurici, .................. 3½.
M. Sig.: Apply with camel’s hair brush.

Treatment of complications. The most frequent complications are bubo, phimosis and paraphimosis. Bubo occurs in about one case in three. The treatment is as follows: Instruct the patient to avoid exercise and to keep off the feet as much as possible. When the gland or glands begin to enlarge, put the patient to bed and apply the ice bag, keep the bowels open with some simple cathartic, and give a light diet. In addition, have him rub into the skin covering the gland, with gentle friction, for fifteen minutes, three times each day. The use of pressure by means of a bandage or the painting over the gland with collodion often prove effective. If the inflammation goes on to the point of suppuration, the treatment becomes surgical and one of two procedures may be followed. The gland may be punctured at one or more points with a sharp pointed bistoury and allowed to drain, which at times is a slow process, or the skin may be incised longitudinally, directly over the gland and the entire gland enucleated, and the resultant cavity filled with boric acid and sutured.

Phimosis is often an irritating condition to deal with, in that if the ulcers are situated beneath, they cause the prepuce to swell to an enormous size and thus render the treatment difficult and the drainage poor, on account of being unable to get at the lesions. This condition is best treated by the use of the flat or so called duck billed syringe, which may be introduced under the foreskin into the preputial cavity. Antiseptic solutions are thus introduced and any of the following will do good work: Hydrogen dioxide water, bichloride of mercury (one in 4,000), or argyrol solution, ten per cent. I like to use any of the first three mentioned or a saturated solution of boric acid, and follow up with the argyrol solution. This process of irrigation should be carried out at least two or three times each day. In addition to the use of irrigation, the use of very hot water should be made to reduce the swelling. The penis should be immersed every few hours for a period of fifteen minutes. When the above outlined treatment does not accomplish the desired results and it is seen that the inflammation is not decreasing or is increasing, then the case should be treated surgically. A dorsal incision may be made, but as a rule two lateral incisions should be made, thus giving access to the entire preputial cavity and exposing all lesions which may be contained within it. The dorsal incision does not expose the lesions if they happen to be in the region of the frenum. After making the two lateral incisions, the lesions may be treated as has been previously outlined and the two flaps turned back upon the glans and dressed with gauze in such a manner as to protect the cut surfaces. The operation of circumcision should not be attempted at this time, as there is too much edema of the tissues to get a result to be proud of. This operation may be performed later.

Treatment of paraphimosis. Treatment of paraphimosis should, in the first place, be prophylactic, in that when the prepuce is in a swollen condition, it should be retracted with care or better not at all. When this condition is a reality the treatment is as follows: Irrigate the parts frequently with a hot solution of carbolic acid (two per cent.) or a hot sublimate solution (one in 2000). In addition, immerse the penis two or three times each day in either of the above mentioned solutions, made as hot as can be borne. The constricting bands may be cut, but this should be avoided if possible. In most cases the irrigation and immersion treatment will prove effective. In conclusion, it might be well to suggest a few "don’ts" in connection with the treatment of this trouble.

1. Don’t give mercury and treat as syphilis.

Wait until you know syphilis to be present.

2. Don’t use ointments in the treatment of this trouble (as a broad rule).

3. Don’t let fear of infection to cut surfaces prevent you from cutting a phimosis, when you need drainage from the preputial cavity and can get it in no other way.

4. Don’t let moisture accumulate about lesions. Keep them dry as possible, as the drier they are kept the more quickly they heal.
Dr. Enoch S. Fulton, of New Therin, La., states

That the treatment of chancroids may be divided into the prophylactic, abortive, and palliative, and the treatment of the complications. Of the prophylactic treatment, little chance can be had to employ it as the practitioner does not see the victim until the infection has already begun; he may then, in his role of educator, however, advise the patient as to his actions in the future. The bathing of the parts, after intercourse, with any alcoholic solution—whiskey, bay rum, or any of the many antiseptic solutions on the market containing thymol, menthol, etc., while not germicides, will stop the growth of any infection which may be present. The use of bichloride of mercury tablets for the preparation of an antiseptic wash, although one of the best, is to be condemned for the laity for the reason that the inexperienced, in their anxiety to prevent infection, will make the solution too strong and thus cause inflammation of the glans and the prepuce, which, while not as serious a condition as the chancroid, is more painful. Another reason for condemning the use of the tablet, is that the taking of them for suicidal purposes is becoming too popular to justify their common use when there are so many other things which will serve the purpose as well.

Abortive treatment. The abortive treatment is to be employed should the chancroid be seen in the first seven days. My procedure in the abortive treatment is as follows: Cleanse the sore of its exudates by the use of hydrogen dioxide and a hot antiseptic solution of any nature; apply a piece of absorbent cotton saturated with a four per cent. solution of cocaine to the sore for five or ten minutes; or apply phenol until the surface of the sore turns white. The latter is as good an anesthetic as any, but is more painful than the cocaine. Having the surface of the sore thoroughly anesthetized, apply nitric acid in sufficient quantity to cauterize the whole surface of the sore, being careful not to burn any tissue but the ulcer. Guard against the latter by coating the tissue around the sore with sterilized petrolatum. Having finished the cauterization, dress antiseptically with any antiseptic powder, my preference being thymol iodide. Leave this dressing intact for five days; then if the ulcer was thoroughly cleansed it will be practically cured when you dress it the second time.

Palliative treatment. After seven days the abortive treatment does no good and in reality makes a bad matter worse. Where there was only one sore a few days ago, there are now probably several of different sizes and in different stages of development. The tissue around the first sore is probably undermined and there may be connections with it and the smaller surrounding ones. The Ducrey bacillus is now found (demonstrated by culture) all over the area surrounding the ulcers. It is obvious then, that the use of the cautery would merely enlarge the ulcers to have them reinfected by the surrounding tissue. Then, given a chancroid passed the stage where it can be aborted, the treatment becomes one of cleanliness and protection. As to the cleanliness, nothing surpasses plain hot water. Hot water properly applied is not only antiseptic, inhibiting the growth of the organisms, but it creates a hyperemic condition in the parts, thus increasing the number of the white corpuscles and aiding materially in effecting a cure. If your patient is an intelligent one (and the vast number are not), this method of treatment can be explained to him in such a way that he will be impressed enough by it to carry out your instructions carefully. The soaking of the parts in hot water, as hot as can be borne, for fifteen minutes out of every two hours, will effect a cure in every case very promptly without further medication. The average patient, however, with this trouble does not take kindly to anything he has to do for himself, so it becomes necessary to prescribe something that will be less trouble for him to use. For this purpose there is no drug better than mercury in the form of calomel or gray powder. After having cleansed the sore with hydrogen dioxide or some antiseptic solution, dry it thoroughly and fill it with the powder, covering with absorbent cotton secured in position by strips of adhesive plaster.

Treatment of the complications. Under the treatment of the complications comes the treatment of those conditions arising from phimosis and paraphimosis; cellulitis, bubo, and suppuration. In phimosis where the sore is behind the corona or on the inner surface of the prepuce, in fact, in any position in which the prepuce will interfere with the treatment, the authorities recommend the making of a dorsal incision through this structure and pulling the flaps back out of the way. Taylor recommends the making of two lateral incisions for this purpose. I have had better results by completing the circumcision at once. This procedure followed by rest in bed and the applications to the parts of hot bichloride of mercury packs will effect a cure very promptly and will save the trouble of a secondary operation. I have never used the dorsal or lateral incision without having a cellulitis following in the flaps.

Conditions of sloughing or phagedena call for the use of the cautery, and if you would be successful, do not be afraid of cauterizing too much. Some authorities advise that when the sores on each side of the frenum have sloughed through, to cut the frenum, but my practice is to leave it entirely alone, and the results I have obtained in the past justify my action in this regard.

The glands in the groin must be closely watched and the patient advised against any violent exercise. Should adenitis occur, place the patient in bed and put an ice bag over the inflamed glands. Do not paint with iodine in hopes of "scattering" the inflammation, for it does no good and roughens the skin, so that, if abscess should occur, the surrounding skin will be sure to become infected. In the event of abscess formation in the glands, incise them and drain. Should the whole chain become infected, give a general anesthetic and dissect them out, removing the entire chain. Dress antiseptically as an open wound, and provide abundant drainage.

The chancroid in the female is to be treated along the same general lines as in the male. Extreme care should be given to the making of a diagnosis of chancroid of the cervix. Microscopi-
cal examination of a section of the tissue should be made to make sure you are not dealing with a carcinoma.

*(To be continued.)*

**Therapeutic Notes.**

**Treatment of Anal Fissure.**—Roux, in Lyon medical for July 13, 1913, is stated, on the basis of eight cases treated by him, to approve strongly of a method first recommended by Lewis, of Brooklyn, which consists in applying to the fissure, held open for the purpose, a saturated solution of potassium permanganate. Sharp pain is induced, but this may be avoided or at least greatly lessened by previous application for a few minutes of a small tampon dipped in a two or three per cent. solution of cocaine hydrochloride. The application of permanganate solution is made daily. Cure results frequently in two or three days.

**Treatment of Breast Lymphangitis in Nursing Women.**—L. Dubrisay, in Journal de médecine de Paris for April 10, 1913, strongly recommends the repeated use of a Bier cup in cases of breast lymphangitis. This measure may be substituted with advantage for manual expression in cases where there is accompanying inflammation of the milk ducts. The cup not only favors the outflow of milk without causing any local irritation, but by inducing venous hyperemia, relieves pain. Hot, moist compresses should be applied to the breast in the intervals between successive cuppings.

**Treatment of Burns.**—Vargas, in Journal de médecine de Paris for September 27, 1913, recommends the following application in burns:

<table>
<thead>
<tr>
<th>R</th>
<th>Finely powdered neutral dextrin.</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Tin cuture of aloes, .............</td>
</tr>
<tr>
<td></td>
<td>Diluted alcohol, ..................</td>
</tr>
<tr>
<td></td>
<td>Lead nitrate (C. P.), ..........</td>
</tr>
<tr>
<td></td>
<td>Phenol, .....................................</td>
</tr>
<tr>
<td></td>
<td>Tannic acid, ......................</td>
</tr>
<tr>
<td></td>
<td>Cherry laurel water, ..........</td>
</tr>
<tr>
<td>M. Sig.:</td>
<td>To be painted over the burned area.</td>
</tr>
<tr>
<td>Another useful combination is:</td>
<td></td>
</tr>
<tr>
<td>R</td>
<td>Lead carbonate, ...........</td>
</tr>
<tr>
<td></td>
<td>Powdered gum arabic, ..........</td>
</tr>
<tr>
<td></td>
<td>Sodium bicarbonate, ..........</td>
</tr>
<tr>
<td></td>
<td>Linseed oil, ...................</td>
</tr>
<tr>
<td>Make a cream.</td>
<td></td>
</tr>
<tr>
<td>Sig.:</td>
<td>To be applied after opening the blisters.</td>
</tr>
</tbody>
</table>

This preparation should not be used repeatedly at short intervals, unless there is suppuration. No signs of lead poisoning have ever been observed after its use, probably owing to the gum arabic it contains.

**Hexamethyleneamine Used to Prevent Postoperative Tympany.**—G. P. LaRoque, in the Therapeutic Gazette for July, 1913, states that he has employed hexamethyleneamine for the purpose referred to in over 300 operative cases, including many with adherent pelvic disease, large uterine and ovarian tumors, all types of hernia, appendicular abscess, and bile tract infection—all prone to postoperative tympanites—with the result that the symptom appeared in sufficiently marked form to require other measures only in four cases of the total number. In two of these four cases, moreover, only small amounts of the drug had been used.

The procedure advocated is to administer ten grains (0.6 gramme) of hexamethyleneamine in a glassful of water every two hours, between meals, and while the patient is awake, for two days previous to operation. The evening before, or the morning of the operation, the usual bowel cleansing with castor oil and enemata is effected. Immediately after the operation, the nurse infuses 120 grains (8 grammes) of hexamethyleneamine in a quart (litre) of drinking water, usually without ice, and as soon as the patient is thirsty small quantities of this, at a time, are given, the amount being, however, cautiously increased as the stomach becomes retentive. In this way the patient usually takes and retains at least a quart of water with the 120 grains of the tasteless drug during the first twelve to twenty-four hours. By this time he can commonly retain a glassful of water at a time, and ten grains of hexamethyleneamine in a tumblerful of water are administered every two hours until between sixty and 120 grains have been given a day, for three days after the operation. At the end of this time the drug is discontinued and the customary postoperative bowel cleansing performed. If excessive vomiting is present or if for any purpose water is given by bowel instead of by mouth, the drug is dissolved in the hot water or saline and thus administered.

**Pipe Clay as a Gastric Remedy.**—Léon Meunier, in Gazette médicale de Paris for July 27, 1913, states that kaolin (pipe clay, official as kaolinum) bears comparison well with bismuth subnitrate as a reliever of gastric pain. Mixed with water, the clay forms a paste which adheres to the stomach wall even more strongly than the bismuth salt. If kaolin is given to a normal individual, and a few days later bismuth, washing out the stomach twenty-four hours after their ingestion will show that the bismuth is entirely gone while traces of kaolin are still present. Examination of the stomach contents demonstrates that gastric acidity is much lower after kaolin than after bismuth. The stools are not blackened by kaolin as they are by bismuth; intestinal hemorrhage is therefore not masked by it.

**Use of Suprarenal Extract in Hiccough.**—J. Ségal, in Journal des Praticiens for August 23, 1913, reports a case of obstinate hiccough in a patient suffering from renal colic, in which, after large doses of bromide, chloral hydrate, chloroform, and cocaine, injections of morphine, gastric lavage with silver nitrate solution, spraying ethyl chloride on the epigastrium, and even general chloroform anesthesia failed to bring relief in the course of eleven days, administration of suprarenal extract proved promptly effective. The patient took ten drops of the one in 1,000 solution; at once the hiccough became milder and less frequent, and upon repeating the dose half an hour later, the symptom completely and permanently disappeared. The action of the drug in relieving hiccough is compared by the author with the “anti-spasmodic” action it is well known to exert in bronchial asthma.
DR. HERMANN M. BIGGS RETIRES FROM THE DEPARTMENT OF HEALTH.

In the retirement of Dr. Hermann M. Biggs as chief medical officer of its department of health, the city of New York sustains an incalculable loss, for to him, more than to any other individual, are due the extraordinary achievements of its public health work. Thanks mainly to Doctor Biggs's initiative, the discoveries in bacteriology in the eighties were used to work a revolution in the methods of public health administration in this city, thus placing this important work on a scientific foundation; and since then, through his tireless efforts, the medical work of the health department of the city of New York has constantly been kept abreast of the advances in scientific medicine. In fact, so keen an observer as Koch, on the occasion of his visit here in 1908, remarked that though so many important discoveries in medicine emanated from Germany, their practical application to public health work was more prompt and further advanced in this country. In particular, he mentioned the work done by the New York city health department in providing for the microscopical examination of sputum for tubercle bacilli, in examining cultures for diphtheria, in manufacturing and distributing free to the poor, diphtheria and tetanus antitoxin, and in examining blood for the Widal reaction. Since that time the department of health has begun the manufacture and distribution of bacterial vaccines, and, still more recently, aids physicians in the diagnosis of venereal infections by making, free of charge, Wassermann reactions for suspected syphilis and complement deviation tests for gonococcus infection.

Not only with respect to laboratory work, moreover, has public health administration undergone a revolution. Following the intensive studies made as part of the tuberculosis campaign inaugurated in this city in 1892, attention was directed more and more to the social environment as a factor in public health, and in this feature of the work Doctor Biggs took an active and leading part.

Curiously, much of the work here mentioned has been accomplished in the face of active opposition on the part of the medical profession, and it is only now that we fully realize how fundamentally sound are the policies logically developed by Doctor Biggs and his associates. Those who know how extensively the example set by the Department of Health of the City of New York has been followed, not only in this country but also abroad, will perhaps have some idea of the enormous influence exercised on the public health by our friend and colleague, Dr. Hermann M. Biggs.

POISONED NEEDLES IN MEDICAL JURISPRUDENCE.

A bold attempt on the person of a woman by a man with a poisoned needle, however fictional it sounds, is not entirely incredible. Such a thing is possible, though not probable, and that it has occurred some eminent authorities have not had difficulty in believing. Eulenburg, for instance, says, "Nobody will utterly deny the possibility of criminal poisoning by means of the hypodermic injection." The only case recorded, however, was discussed many years ago in the Allgemeine medicinische Central-Zeitung (1864, p. 170) by Beer, but his report has been left to slumber in the files of that periodical. We shall not attempt to bring it to light, for the duty of reticence in such matters is clear, as Beer himself pointed out. "Crime," he says, "is always engaged in studying every new discovery in order to use it for its own purposes." He is speaking of the hypodermic method. Again, Eulenburg, writing in 1875, says that in Bengal needles poisoned with Abrus precatorius have been employed by assassins. This hideous device is the nearest approach which is described in serious literature to the events that are supposed to have happened here.

The incompatibility between our knowledge and these alleged occurrences is worth a careful exposi-
SALVARSAN IN PERNICIOUS ANEMIA.

Although arsenic in organic form is regarded as a specific in the treatment of pernicious anemia, clinicians who have had a large number of these cases, know full well that "recovery" means, in most instances, but a more or less prolonged period of marked improvement, unless the cause of the disease is discovered and removed. Byrom Bramwell, after trying the Ehrlich-Hata organic arsenical, salvarsan, in seven cases, six of which showed marked improvement, held that this agent would probably be found a more efficient remedy than inorganic arsenic given by the mouth, and indeed than any other form of treatment. An "uninterrupted recovery" in a severe case was reported by Hobhouse, and another by Friedländer. It was expressly stated that the latter case had proved refractory to Fowler's solution; the recovery was sustained, however, by the use of sodium cacodylate. Conversely, Charteris found, in two of his three cases, that salvarsan produced such a degree of anemia as to bring about death within three weeks, while the third was neither improved nor harmed. In Maynard's case, there was a definite increase in the number of red corpuscles for a fortnight, at the end of which period a second dose was given; but examination a week later revealed a diminution in these blood cells. Other reports are available in literature, but they are, as a rule, conflicting and unsatisfactory. There appears to be good ground, however, for the belief of some observers that the use of salvarsan in pernicious anemia is by no means free from danger.

To test the question, Doctor Thomas R. Boggs (Johns Hopkins Hospital Bulletin, October, 1913) tried salvarsan in four cases at the Baltimore City Hospital. All showed a favorable reaction to the drug as to the regeneration of the blood and relief of the symptoms. One was a most remarkable apparent cure of a patient in his fifth relapse, who had been quite unresponsive to Fowler's solution and had shown only a very slight regeneration after four months of sodium cacodylate injections. Under intravenous administration of salvarsan in doses of 0.3 gramme every four weeks, he showed a steady rise in the blood count.

Another patient, whose nervous symptoms preceded the change in the blood picture by some months, proved very responsive to salvarsan, his blood count rising from 1,100,000 to 3,400,000 red cells in twenty days after the first dose of 0.3 gramme intravenously, and eventually reaching 4,800,000, with eighty-five per cent. of hemoglobin. This patient gave no history of syphilis, and Wassermann reactions in the serum and cerebrospinal fluid were negative. The other two patients, both negative to tests for syphilis, received but one injection each, and were greatly improved, with an average rise of 2,000,000 red cells when they left the hospital.

There was, as a rule, a sharp febrile reaction, lasting from six to twelve hours after each injection, in contrast to the very mild or absent reac-
tion in syphilitics. All precautions were taken with regard to technic and size of dose.

On the whole, it would seem that some cases, at least, of pernicious anemia can be decidedly benefited by the use of salvarsan, especially those in which a luetic history can be traced. Full trial should, however, be made of Fowler's solution or the cacodylates before exposing the patient to the dangers which the use of this new remedy undoubtedly entails when true pernicious anemia is present.

THE TRUTH ABOUT NUCLEOPROTEINS.

Medical literature is rich in references to nucleoproteins and their use as antigens. One result of efforts made to obtain the active antigenic principle of cells has been the selection of substances dissolved in weak alkaline solutions and precipitated by weak acid. These substances have been called nucleoproteins in the belief that they were protein substances derived from the nuclei of the cells and assumed to be the most specific of the cell constituents. The well known work of Beebe is a case in point. He has prepared a serum alleged to have therapeutic value in goitre, by the injection of animals with extracts of the thyroid assumed to be the specific nucleoproteins. An attempt has also been made to treat cancer with homologous tissue extracts prepared by similar methods.

In the realm of bacteriology, Lustig and Galeotti have been for several years working with bacterial extracts which they have called nucleoproteins. These have been employed for the injection of animals to produce specific therapeutic serums for a great variety of diseases. The contribution of Galeotti in Report of the International Plague Conference, Mukden, April, 1911, is noteworthy.

At the present time many workers in the field of immunology are trying to find a vaccine representing as nearly as possible a pure antigen. In these researches the nucleoproteins appear attractive, especially to those who, lacking a profound knowledge of protein chemistry, take at their face value statements found in the literature dealing with these substances. To such persons the value of the recent critical review by Gideon Wells in the Zeitschrift für Immunität, xix, 5, 1913, cannot be overestimated; he points out that while the nucleus is undoubtedly a vital part of the cell, it does not necessarily follow that the proteins of the nucleus are more differentiated than those of the protoplasm. We do not know what proportion of a nucleus may be nucleoprotein, and we do not know how much of the cell outside the nucleus is nucleoprotein; furthermore, we do not know whether or not the nucleoprotein is more important or more characteristic chemically than other constituents of the nucleus. Hammarsten holds that there is a considerable proportion of nucleoprotein in the extranuclear structure of the cells.

Wells believes that the assumption that a precipitate obtained by the extraction of cells with an alkaline solution and precipitation with a weak acid yields pure nucleoprotein, may well be questioned. Not only would nucleoproteins and nucleins be dissolved in the alkali, but also mucin, nucleoalbumins, probably various glycoproteins, besides the mucins, simple globulins and albumins, and alkali albuminate formed by the action of the alkali upon the native proteins. Upon acidification all these, with the exception of simple albumin, might be precipitated and the mixture, together with many other undetermined cell constituents, would constitute the material commonly called nucleoprotein. For the purification of the precipitate, it is recommended that it be redissolved in alkali and reprecipitated by dilute acid; this may be repeated several times.

As such purifications are continued, the action of the acid and alkali will alter the character of the original nucleoprotein, so that the proteins become insoluble and leave the nuclein and nucleic acid in increasingly large proportions. It is obvious that the percentage of protein in the final precipitate will vary according to the conditions existing at the time.

From a consideration of the nature of the substances commonly called nucleoproteins we learn that there are evidently three different substances in question with regard to immunity reactions. The first, nucleic acid, is nonprotein, practically a glucoside; second, the nucleins which are compounds of a doubtful character, but which seem to consist of nucleic acid bound firmly to proteins; third, the nucleoproteins which seem to be very indefinite and loose compounds of any or all the proteins of the cell with either nucleic acid itself or with the nucleins. Obviously, the nucleoproteins are artificial substances of uncertain and doubtful character, owing their antigenic properties chiefly if not entirely to the loosely bound proteins. Wells continues: "To ascribe to these mixtures any particular cell or organ specificity would seem to be preposterous, for they must react as do the proteins they contain in so far as these proteins have not been denaturized by manipulation. That any particular protein is specifically combined with nucleic acid to form nucleoproteins there is no evidence whatever. But, on the contrary, there is evidence that many sorts of proteins may thus be united; undoubtedly this is the case with the living cell."

Studies of preparations made after Woolridge's method, but reprecipitated several times, show that
they consist practically of nucleins, and such preparations are incapable of causing an animal to produce antibodies; but the original first precipitates, which are rich in proteins, do have antigenic properties. It therefore seems that the antigenic properties of nucleoprotein preparations depend simply upon the proteins present in these preparations, and are not in any sense a characteristic integral part of a definite substance, nucleoprotein, but rather an adventitious impurity, the character and amount depending entirely upon the method of preparation.

REGULATING THE SALE OF BICHLORIDE TABLETS.

During the year 1910, out of 825 suicides reported in New York, 274 were committed by means of illuminating gas, and 228 by gunshot; in 1911, illuminating gas was the agent used in 256, and the pistol in 201 cases. The deaths from these two agents alone, therefore, amounted to fifty-nine per cent. of the total deaths by suicides in the two years named. During those two years the number of suicides committed by means of poisons amounted to fourteen per cent. of the whole number. The poison most used in 1910 was carbolic acid, forty-four suicides having been committed with this drug in 1910 and thirty-four in 1911. The increase in the use of mercury bichloride as a disinfectant probably accounts for an increase in the number of suicides in which this agent was used, from two in 1910 to fifteen in 1911. Between January 1st and November 15th of the current year, fifteen cases of suicide by means of mercury bichloride were reported and six deaths by accidental poisoning.

In order to prevent these deaths by accident as far as possible the Department of Health of the City of New York, on December 6th, adopted an ordinance amending the penal code under which it is made illegal to sell corrosive sublimate at retail in dry form, except in colored tablets individually wrapped, the wrapper to have the word “poison” in plain letters conspicuously placed, and dispensed in sealed containers of glass labeled with the word “poison” in red letters. Tablets containing one tenth of a grain or less are exempt from this provision. It seems desirable that some additional restriction should be thrown around the sale of this poisonous substance, and the wrapping of the tablet seems admirably calculated to protect the public from poisoning by inadvertence. It seems, however, that some provision should be made by which the pharmacist could keep in stock the uncolored dry powder to dispense in prescriptions, in which this substance is called for either in solution or in ointment.

Philadelphia Medical Examiners’ Association.—Dr. Paul Fitzgerald, of Newark, N. J., addressed the members of this association, at their annual meeting on Tuesday, December 2d. Dr. F. K. Collins was elected president. Dr. Max Goep, vice-president, Dr. Ernest W. Kelsey, treasurer, and Dr. J. H. Grasse, secretary.

Pelagra in Pennsylvania.—The second death from pelagra in Pennsylvania is reported to have occurred in Lancaster on Sunday, December 7th. The victim was a druggist, of Quarryville, twenty-six years of age, whose illness of several months’ duration puzzled the physicians a long time before a correct diagnosis was made.

Campaign to Raise Funds for the Washington Heights Hospital.—A ten day campaign to raise $2500 for the Washington Heights Hospital, New York, which was started on Monday, December 8th, with two hundred workers, twenty committees, and as many subcommittees. The money is to be used for the erection and equipment of an up to date building for this hospital which serves an ambulance district of 150,000 population. It is a nonsecular institution.

Somerville, Mass., Medical Society.—Dr. Frederic J. Cotton, of Boston, was the guest of honor at the annual meeting of this society, held on the evening of December 3rd. He delivered an address on “The Characterization and Classification of Bacterial Types,” which was illustrated by lantern slides. The following officers for the ensuing year were elected: Dr. Ralph F. Hodgen, president; Dr. Frederick N. Stephens, vice-president; Dr. William Blake, secretary-treasurer, Dr. E. D. Pillsbury, presiding.

Society of American Bacteriologists.—The annual meeting of this society will be held in Montreal, Canada, on December 31st and January 1st and 2d, under the presidency of Professor C. A. Window, of the University of Pennsylvania. The address of the president, on The Characterization and Classification of Bacterial Types, will be delivered at the annual dinner, which will be held on the evening of January 1st. The programme has been divided into the following topics, each of which will be treated of by a noted bacteriologist, sanitary bacteriologist, systematic bacteriologist, techinic, immunity, and pathology. Dr. A. Parker Hitchens, of Glenolden, Pa., is secretary of the society.

American Society for the Study of Alcohol and Other Narcotics.—At the forty-third annual meeting of this society, held last week in Philadelphia, the following officers were elected to serve for the ensuing year: President, Dr. John J. Kindred, of New York; vice-presidents, Dr. A. M. Grasse, of Chicago; Dr. T. A. MacNicholl, of New York; Dr. Tom A. Williams, of Washington, and Colonel L. M. Maus, United States Army; secretary, Dr. C. H. Denton, of Miami, Fla.; assistant secretary, Dr. De Lancey Cooper, of New York; corresponding secretary, Dr. H. Thomas D. Crothers, of Hartford, Conn. and treasurer, Dr. Pitts E. Howes, of Boston.

Medical Association of the Greater City of New York. At a stated meeting of this association, to be held on Monday evening, December 15th, in House Hall, New York Academy of Medicine, the programme will consist of a symposium on intestinal stasis. The subject will be considered from the medical point of view by Dr. William Van Alstyne, from the radiological, by Dr. A. Judson Omlby, and from the surgical by Dr. William Seaman Bainbridge. Doctor Bainbridge’s article will be illustrated with lantern slide demonstrations. The subject will be discussed by Dr. Edward L. Kellogg, Dr. Walter A. Bates, Dr. James T. Case, of Battle Creek, Mich., Dr. Arthur F. Holding, Dr. J. Dion Bogart, Dr. Harold D. Mecker, and others.

Changes in the Constitution of the Rush Society.—In order that the Rush Society of Philadelphia might be more truly representative of its activity, a revision of its constitution and by-laws was voted at a special meeting called recently for that purpose. The changes made were as follows: First, the name of the society has been lengthened to The Rush Society of Philadelphia. The Rush Society. The Rush Society of Philadelphia. Second, the distinction between active and associate members has been abolished and it is now provided that any person interested in the objects of the society may become a member upon the payment of the annual dues of $2. It is believed that by these changes the effectiveness of the lectures in Philadelphia will be increased.
Middle Tennessee Medical Association.—At the annual meeting of this association, held on Thursday and Friday, November 20th and 21st, in Columbia, Tenn., the following officers were elected: President, Dr. G. E. Filbin, Nashville; vice-president, Dr. H. O. Parson, of Columbia; secretary and treasurer, Dr. R. W. Billington, of Nashville. The next meeting of the association will be held in Bell Buckle on the third Thursday of May next.

The Medicine of the Babylonians and Assyrians.—This is the subject of a lecture to be given by Professor Morris Jastrow, of the University of Pennsylvania, on December 16th, at a meeting of the Section in Medical History of the College of Physicians of Philadelphia. His address will include a translation of the ancient tablet lately presented to the college by Dr. training, M. D., of Richard H. Harte, the Assyrian medical code being for the first time revealed. The meeting is open to the general public.

The New York Physicians' Association.—The next meeting of this association will be held on the evening of December 17th at the private branch of the New York Public Library, 121 East Fifty-eighth Street, at nine o'clock. The meeting will be devoted to a consideration of the sociological aspects of defects of hearing and sight, and will be open to nonmembers. All who are interested in the subject will be welcome. The programme will include papers by members, on the following subjects: The Supervision of Sight and Hearing in the Industries, by Dr. C. T. Graham Rogers, Department of Labor, State of New York; the School Campaign Against Eyestrain, by Dr. C. Ward Crampton, superintendent of physical examination department of New York; Economic Significance of Deafness, by Dr. John D. Wright, superintendent of the Wright Oral School for Deaf Mutes. A general discussion will follow, which will be opened by Miss Winifred Holt, of the New York Association for the Blind.

Reception in Honor of Emeritus Professors of Jefferson Medical College.—A reception, preceded by a dinner, was given at the home of Mr. Daniel Baugh, of Philadelphia, on the evening of December 2d, in honor of Dr. William W. Keen, Dr. James C. Wilson, Dr. W. Joseph Herr, and Dr. James W. Holland, all of whom are emeritus professors at Jefferson Medical College. About three hundred physicians attended the reception, among the guests being Dr. Abraham Jacoby, Dr. Robert Abbe, Dr. George B. Horsfall, and Dr. Joseph Gambrell, of New York; Dr. E. C. Conklin, of Princeton University; Dr. Edward Rice, president of the New England Association of Jef- ferson graduates; Dr. William T. Matack, of Wilkes- Barre, Pa.; Surgeon General Charles F. Stokes, United States Navy; Surgeon General H. Torney, United States Navy; Surgeon General Rupert Blue, United States Public Health Service; Dr. Llewellys F. Barker, of Johns Hopkins University; Dr. J. Ewing Mears, of Philadelphia; Dr. James Tynan and Professor Richard Pearce, of the University of Pennsylvania; Dr. James M. Anders, of the Medico-Chirurgical College, and the Rev. Dr. Russell H. Conwell, president of Temple University.

Legislation Relating to Industrial Diseases and Acci- dents.—According to a bulletin issued by the American Association for Labor Legislation, describing the labor laws in various states, the majority of the states have passed new or strengthened old laws requiring the reporting of accidents on railways and in mines and factories. Four new States have required physicians to report cases of occupational diseases, and New York and Connecticut have extended their laws to include brass and wood alcohol poisoning. Laws requiring sanitation, dust and fume removal, and washing facilities in factories were widely adopted, and three great lead using States have enacted new laws. Eighteen states have enacted scientific provisions for protection against trade diseases, particularly lead poisoning. Safety requirements for mines were made more stringent in fifteen States, while twenty-six States demanded greater safety for railroad employees. During the meeting, the Representatives of New York, and Pennsylvania, have reorganized their labor departments, and in over a dozen additional States factory inspection departments have been reorganized and enlarged.

Georgia Surgeons' Club.—At the first annual meeting of this organization of Georgia surgeons, held in Atlanta on November 5th and 6th, the following officers were elected: President, Dr. E. C. Davis, of Atlanta; vice-presi- dent, Dr. Thomas J. McArthur, of Rome; first vice-president, Dr. S. H. Harbin, of Rome. The executive committee is composed of Dr. William S. Goldsmith, of Atlanta, chairman, Dr. G. R. White, of Savannah, and Dr. W. H. Bates, Jr., of Augusta.

Personal.—Dr. Maria Montessori, founder of the educational system which bears her name, arrived in New York from Rome on Wednesday, December 3d. During her stay in the United States she will deliver a series of lectures on her method of education, under the auspices of the Montessori Educational Association, I.O.O.F., Monday evening, December 8th, she lectured in New York, and on the evening of December 9th, in Philadelphia. Her lec- tures are illustrated with motion pictures.

Dr. William Sydney Forster, professor of clinical medi- cine at Johns Hopkins Medical School, has been appointed visiting lecturer in medicine at the Harvard Medical School. During his stay in Boston he will also be visiting physician to the Peter Bent Brigham Memorial Hospital.

Medical Society of the County of Clinton, N. Y.—The annual meeting of this society will be held on Tuesday, November 18th. There was a large attendance and the meeting was in every respect very successful. Papers were read by Major Weston P. Chamberlain, Medical Corps of the United States Army, Dr. J. B. Ransom, American of Rome, and Dr. James T. MacDonald, of the Medical Society of the County of Clinton, N. Y. Dr. R. S. Mac- Donald, of Plattsburg; treasurer, Dr. J. C. McKinney, of Plattsburg; secretary, Dr. T. A. Rogers, of Plattsburg.

Annual Banquet of Phi Epsilon Rho.—Dr. A. C. Tenney, of Chicago, president, at the annual banquet of Phi Epsilon Rho, the national medical fraternity, which was held in Chicago on the evening of November 29th. Among the speakers were Dr. C. G. Fellows, Dr. Leroy Thomp- son, Dr. C. D. Collins, Dr. E. S. Clark, and Dr. H. V. Halbert, of Chicago; Dr. A. C. Buckley, of Philadelphia; Dr. S. G. Schoemaker, of Ann Arbor; Dr. C. B. Conrad, of Cleveland; Dr. A. E. Stepheid, of Cleveland, and Dr. F. A. Loomis, of Ann Arbor. At the business meeting preceding the banquet, the following officers were elected: President, Dr. G. M. Cushing, of Chicago; vice- president, Dr. E. P. Collier, of Chicago; secretary, Dr. Leroy Thompson, of Chicago; treasurer, Dr. L. Manning, of Chicago; directors, Dr. Ralph Bernstein, of Philadelphia; Dr. L. S. Seaman, of New York; Dr. Hurd, of Ann Arbor, and Dr. A. H. Gordon, of Chicago.

Examination for Assistant Surgeons in the Public Health Service.—Boards of commissioned medical officers will be convened to meet at the bureau of the Public Health Service, Washington, D. C., and at the marine hospitals of Boston, Chicago, St. Louis, New Orleans, and San Francisco, on Monday, January 12, 1914, at 10 o'clock a.m., for the purpose of examining candidates for admission to the rank of assistant surgeon in the United States Public Health Service. Notices for the examination at these stations are received in the bureau. Candidates must be between twenty-three and thirty-two years of age, graduates of a reputable medical college, and must furnish testi- monial evidence that they are of good moral character. Candidates are required to take an oral examination in insane or criminal insane experience or mental experience will be considered and credit given in the examination. Candidates must have had one year's hospital experience in the care of mental patients. The examinations are chiefly in writing, and begin with an autobiography of the candidate. The remainder of the written exercise consists of examination in the various branches of medi- cine, surgery, and hygiene. The oral examination includes subjects of preliminary education, history, literature, and natural sciences. For invitation to appear before the board of examiners, and for further information regarding the scope of the examination, address the Surgeon General, Public Health Service, Washington, D. C.
Hypersplenic Destruction of the Blood Corpuscles and Congestion of the Spleen.—Bruno Oskar Pribram reports, from extensive experiments on dogs, that by causing a congestion of the spleen urobilinuria can be produced, an indication of an abnormal destruction of red blood corpuscles. He was unable to excite urobilinuria in other ways, even by the intravenous injection of substances known to be directly destructive to the blood cells. He found in all the dogs that the spleen was enlarged, the splenic vein engorged and varicose, its branches very tortuous, and varicose swellings present in the hilus, together with an abnormally small number of red blood cells, anemia, and urobilinuria. He concludes that the pulp of the spleen is the place where the erythrocytes are destroyed, or are so greatly injured that their further conversion into bile in the liver is accomplished with ease. A factor favoring such a destruction of erythrocytes is the congestion of the spleen. He thinks that we have to deal here with a disease sui generis, which is perhaps caused by the suppuration of the cord during the first weeks of life, through a congestion of the blood in the spleen productive of varicosities, tortuosities, and scleroses of the splenic veins, and an increased destruction of the red blood corpuscles.

Experiences with Weleminsky's Tuberculosis.—Alfred Goetzl says that this preparation has a specific action upon the tuberculous organism which may perhaps be ascribed to the content of mucin. Whether it is able to produce more permanent effects than other preparations remains to be seen.

Critical and Experimental Contribution to the Differential Diagnosis of Diphtheria and Pseudodiphtheria Bacilli.—Markl and Felix Pollak are unable to find any reliable means of distinguishing the true from the false diphtheria bacilli. A fact of more importance concerning the epidemiology of diphtheria is that they found very virulent bacilli in the nasopharyngeal secretions of four out of ninety-one healthy persons who were not known to have been in contact with patients suffering from the disease. Similar bacilli which were not virulent were found in six other persons. The tellurium plate gave the best service for the finding and isolation of the germs.

Bradycardia, Hypotony, Lowered Temperature, Peculiar Muscular Weakness, Tendency to Fainting, Due to Functional Adrenal Insufficiency.—Edmund Hoke reports the case of a woman thirty-two years old who had tired easily, and had suffered from palpitation, dizziness, and sudden perspiration on slight efforts since she had an attack of diphtheria at the age of fourteen. When seen her skin was pale and clammy, pulse scarcely perceptible, rhythmic, fifty-two, heart sounds clear, temperature 35.8° C. Acute vascular paralysis was diagnosed and 0.5 c. c. of a one in 1,000 solution of epinephrin was injected. In fifteen minutes the patient felt well and strong, pulse sixty-two and much stronger. A course of carbonated baths was then prescribed, and the patient seems to be permanently improved, with a pulse of seventy-two and a blood pressure of 110.

The Demonstration of Absorbed Sperma in the Female Organism.—Edmund Waldstein and Rudolf Ekler found in rabbits after cohabitation a ferment that digested testicle tissue, which could not be found beforehand. They are inclined to think that the presence of this ferment may explain certain symptoms in women which have hitherto been thought to be psychical.

Hypertension and Cholesterinemia.—Collatino Cantieri concludes that there is no constant and immediate connection between hypercholesterinemia and an increase of the blood pressure. Arteriosclerotics with increased blood pressure may or may not have hypercholesterinemia, and the same is true of arteriosclerotics in whom the blood pressure is not increased. In general the amount of cholesterin fluctuates greatly, both in different cases and in the same case from time to time, the normal of which is unknown. Nephritics commonly have a hypercholesterinemia, even when there is no increase of blood pressure.
A New Vaccine Therapy for Ozena.—Gustav Hofer and Karl Kohler report a number of cases of ozena which they have treated by injections of Perez's Coccobacillus factidus ozenae. After about eight weeks' treatment the results seem to be excellent. Soon after the first injection, as a rule, the secretion in the nose and pharynx begins to clear and become fluid, then there follows a diminution of the secretion and of the crusts until the latter almost wholly disappear. The same is true of the fetor. Eczema of long standing gets well, and there is an improvement of the dry pharyngitis and of the voice.

Concerning Aids in the Prognosis of Pulmonary Tuberculosis.—M. Weiss says that a study of the lymphocytes aids in determining the prognosis, for in the early stages of the disease the production of these cells is proportional to the energy with which the organism undertakes its defense. Hence the least favorable prognosis is afforded in cases in which the tendency to lymphocytosis is slight. As exceptional demands are made on the lymphocytes by tuberculosis foci in the lungs, they are withdrawn from the circulation in such quantities that the proportion in the blood may fall to five per cent., which is a bad sign. Another bad prognostic sign is the appearance of urochromogen in the urine, for this shows that specific toxic substances are being absorbed. To test for urochromogen, one part of fresh urine is diluted with three parts of water, and a few drops of a one in 1000 solution of potassium permanganate are added. If urochromogen is present the fluid becomes a canary yellow.

Studies of the Coagulability of the Blood, Its Viscosity, and the Number of Hematoblasts in Morbus maculosus Werlhofii.—Otto Steiger found in this disease that the coagulability and viscosity of the blood were greatly reduced, and that there was a strikingly small number of hematoblasts. No favorable effect could be produced on the coagulability by injections of salt, serum, blood, or peptone, but extract of hematoblasts in the form of coagulin quickly arrested hemorrhages from the mucous membranes, such as a persistent epistaxis

Acidity of the Blood in Osteomalacia.—J. Novak and O. Porges find an acidosis of similar nature in normal pregnancy and in osteomalacia, whence they are inclined to think that an increase of the modification of the ovarian function already present in normal pregnancy is the true cause of osteomalacia.

Bone Formation in a Corpus albicans.—Adachi reports briefly a case in which true bone formation was found in a corpus albicans, there being no traces of teratoma or dermoid cyst.

A Case of Combined Lymphatic and Myelogenous Leucemia.—Herxheimer reports in which an instance of lymphatic leucemia of long standing being complicated by an acute myeloblastic leucemia. The case came to autopsy and the findings are given in detail, particularly the results of the blood examination.

Cholelithiasis.—E. Villard and E. Perrin, discussing the differential diagnosis of cholelithiasis, state that icterus appearing suddenly, without a history of former hepatic trouble, should suggest neoplasm as the cause of the obstruction; persistence and lack of variation in the depth of the jaundice, as well as pyrexia or actual hyperthermia are also characteristic of neoplasm, whereas the opposite conditions obtain in cholelithiasis. The law of Bard and Pic, viz., that the gallbladder is small in cholelithiasis and large in neoplasm, is of some value in the differentiation, though numerous exceptions occur. As regards treatment of cholelithiasis the authors advocate early surgical inter-
vention, stones in the bile duct only infrequently undergoing spontaneous elimination, and exposing the biliary passages to infection and obstruction. Operation in early cases is a simple matter, but entails grave risk when the bile tracts are badly infected and the liver parenchyma impaired. The authors report forty cases operated in of cholecithiasis, with a mortality of forty per cent.; many of the patients, however, were operated on very late.

November 9, 1913.

Amyotrophic Tabes.—Drey and Malespine divide cases of muscular atrophy occurring in tabes into two groups: 1. Cases of atrophy due to central lesions—small focci of myelitis due to local pathological processes, probably of vascular nature—and generally manifested in localized paralyses, as of the tongue or extraocular muscles; 2, cases of neuritic atrophy, due either to true peripheral neuritis resulting from complications of the original disease, or to anterior radiculitis arising through extension of the tabetic process from the cord itself to the nerve roots; each of these forms is diffuse and progressive in type, but the second alone constitutes a complete clinical symptom-complex, and the name “amyotrophic tabes” should be exclusively reserved for it. The author reports a case of this last variety in which progressive muscular atrophy during sixteen months suggested a multiple neuritis, and the signs of tabes were limited to a zone of hypopthesia around the thorax, slight ataxia of the upper limbs, and incontinence of urine. Mercury and salvarsan brought about temporary symptomatic improvement, but cachexia rapidly increased, nevertheless. An account of the autopsy findings, including the results of histological examination, is given. There were found sacral meningitis, sclerosis of the posterior columns and of the anterior nerve roots, slight perinuclear chromatolysis in the anterior horn cells, and a mild degree of interstitial neuritis in the sciatic and other nerve trunks.

PARIS MÉDICAL
November 8, 1913.

False Varices.—J.J. Daussot and P. Lhuillier assert that there is mistaken for deep varicose veins what is merely a chronic cellulitis of the legs and thighs. The condition is met with especially in rheumatic, gouty, or emphsematous patients, as well as in individuals apparently suffering from disordered excretory function of the skin, whether of circulatory, renal, or nervous origin. In addition to the heaviness, edema, cramps, and difficulty of walking present in varicose veins, points of superficial tenderness without evident fibrosis, and later areas of snowlike crepitation and tender nodules, the latter sometimes disposed in chains, are noted when the skin is lifted and the two component layers of the fold gently rubbed together by rolling between the fingers. Another characteristic sign is a white, hard, and painful edema. In all cases of suspected deep varices the subcutaneous tissues should be palpated as described, for if cellulitis is responsible for the symptoms the measures ordinarily employed for varicose veins will prove quite useless. The cellulitis can be readily overcome, and with it insomnia, anorexia, loss of weight, etc., by measures having for their object to promote elimination of toxic wastes and by gentle, systematic massage of the region affected. Hydrotherapy, in the form of affusions, packs, or baths in water the temperature of which is progressively lowered, as well as partial baths in superheated air or electric light baths, may be valuable adjuvant measures. The authors report five cases illustrating the efficacy of the treatment referred to in these cases.

Hemp or Cotton Plaster Dressings in the Treatment of Fractures.—Dupuy de Frenelle prefers these dressings to the thick form of plaster dressing ordinarily employed because they permit of palpating the bony fragments while the plaster is hardening, thus insuring good ultimate position. The hemp strands, which should be as fine as possible, may be combed before using and should then be disposed in small bundles of the thickness of the finger and of suitable length. The bundles are covered with the plaster and then placed independently over the area to be covered, one end being secured by a turn of bandage while the rest of the bundle is spread out and adapted over the fractured bone and adjacent tissues. By using a series of overlapping bundles the dressing can be made as broad as may seem desirable. Where very firm support is necessary, a thick plaster dressing of the ordinary type can be added after the hemp dressing has become dry, or on the following day. Short bands of some absorbent material may be wrapped in series around the plaster dressings to accelerate hardening.

PRESSE MÉDICALE.
November 8, 1913.

Cure of Experimental Tetanus in Guineapigs.—M. A. Ruffer and M. Crenidiropoulou found that in guineapigs to which a fatal dose of tetanus toxin had been given, intramuscular injection of a mixture of antitetanic serum and an extract of the muscles of guineapigs that had already succumbed to tetanus retarded death by three or four days as compared with control animals, whereas injection of either component of the mixture alone on the contrary hastened death. Where the mixture was made in the proportion of four parts of serum to six of muscle extract, was allowed to stand at ordinary room or body temperature for some hours before injection, and was administered intraperitoneally, sixty per cent. of the guineapigs entirely recovered from the tetanic intoxication, while an additional proportion showed marked symptomatic improvement, only to die later of cachexia. The active body in the extract of tetanic muscle was found to be a substance precipitable by alcohol. The authors conclude that in the muscles of tetanic animals there are formed several principles, some favoring the effects of tetanotoxin and the others nulling them. Antitetanic serum is an incomplete remedy, requiring for efficacious action the addition of other substances, which substances are in part found in the muscles of tetanic animals.

JOURNAL D'UROLOGIE.
May, 1913.

Amyloid Degeneration of the Kidney in the Tuberculous.—E. Rist and L. Kindberg found in twelve cases of this disease that the proportion of urea and chlorides is low and the urea index (Am-
hard) is also low. This was a disturbance in function exactly the reverse of that of nephritis. The amyloid degeneration seems to be the result of serious changes in the blood with no connection with preexisting kidney inflammation. The liver, spleen, and adrenals show amyloid degeneration before the kidneys. The report is founded on twelve autopsy cases.

Postoperative Hiccough a Sign of Uremia.—G. Marion has had six postoperative cases with hiccough and considers it an early symptom of uremia. The first of his patients died ten days after prostaticotomy. Death was due to exhaustion after ten days of hiccough. His second patient with hiccough refused all food and took but a few sips of tea or water for five days. At the end of that time the hiccough subsided and the patient recovered. He allows such patients nothing but a little water for four days and then milk. He believes it is very dangerous to give such patients nitrogenous diet.

June, 1913.

Recurring Profuse Hematuria with Ureteral Colic, the Only Symptom of Cancer the Size of a Cherry.—E. Jeanbaut and Etienne report a case in which the patient gave a history of recurring profuse hematuria. The first hematuria occurred eight months before he was first seen. On cystoscopy the blood was seen coming from the left kidney. No tumor could be palpated and a radiogram showed nothing. Examination of the nephrectomized kidney showed a cancer as large as a cherry in the lower pole.

July, 1913.

Renal Tuberculosis in Children.—J. Oraison has collected but forty-eight cases from the literature of kidney tuberculosis in children. He adds three of his own. One of his cases was apparently cured by nephrectomy. The symptoms in children are the same as those in the adult, with the exception that children are much more liable to incontinence of urine. One of his patients was apparently healthy, the only symptom being terminal hematuria and a large tender kidney. The early symptoms in this case were frequent urination and a very limpid urine. He regards this limpid polka-kuria as an important sign of incipient tuberculosis at any age.

Renal Hematuria after Nephrectomy.—Pena reports twenty-two cases of hematuria occurring shortly after nephrectomy for tuberculosis. The author has not decided what the hematuria is due to, but the prognosis should always be guarded as the bleeding may come from a tuberculous process in the remaining kidney.

September, 1913.

Radium in the Treatment of Cancer of the Prostate.—O. Pasteau and Degrais have used radium in the treatment of cancer of the prostate and conclude as follows: The radium may be applied to the cancer through a suprapubic or a perineal incision, or by means of a urethral catheter. They believe that the radium treatment may so reduce a prostatic cancer that an inoperable case can become operable. It stops hemorrhage and completely eradicates secondary glandular involvement.

Ureterovaginal Fistula Following Abdominal Hysterectomy Healed by a Retained Ureteral Catheter.—A. Boeckel reports a case in which eighteen days after hysterectomy for carcinoma the patient complained of urine in her vagina. This was proved not to come from the bladder but from the left ureter. At first a ureteral catheter could not be introduced, but a few days later a small ureteral catheter was inserted as far as the pelvis of the left kidney. This was left in place, but removed at intervals for larger catheters, for a period of seventeen days. The kidney was irrigated with silver nitrate solution. She returned four months later completely well. A large sized catheter was passed up to the kidney pelvis.

REVUE DE CHIRURGIE.

October, 1913.

Curved Radius.—A. Binet and M. Mutel report a case of successful operative correction of Madelung's deformity or radius curvus. The case was, as is usual, in an adolescent with a history of rickets, and showed the three characteristic skeletal changes, viz., luxation of the head of the ulna on the dorsal surface of the wrist, apparent subluxation of the proximal portion of the hand, and an incurvation, with dorsally directed convexity, of the lower half of the radius. The procedure carried out and recommended consists in oblique osteotomy of the radius above the wrist through an incision on the dorsal surface of the forearm, leaving a small thickness of the bone uncut, to be dealt with by osteoclasis; lengthening of the radius if required, by forcibly drawing the hand to the ulnar side, as in the reduction of a Colles's fracture; and hyperextension of the hand on the wrist, to correct the curvature. A palmar splint extending from above the elbow to the finger tips is then worn for a month.

Temperature of the Tissues during Treatment by Hot Air, Diathermy, and Electrocoagulation.—M. Grunspon found by a thermoelectric method that the highest temperature of air that can be borne in direct contact with the skin for two to three minutes is only from 40° to 41°. At 42° the pain is intolerable and a second degree burn immediately results. During the same experiment, however, the air two centimetres from the skin will be found to be at 70° to 80°. In the subcutaneous tissues the rise of temperature produced was only 1°, and in the muscles, nil. In diathermy, the subcutaneous temperature was found to rise after fifteen minutes from 32° or 33° C. to 40° or 40.5° C.; any further rise caused intolerable burning, necessitating interruption of the experiment. Electrocoagulation in two cases of breast cancer caused a rise of temperature in the tumors at a depth of from two to three centimetres to 60° or 65° C. within a period of one and a half to two minutes.

BRITISH MEDICAL JOURNAL.

November 22, 1913.

Anaphylaxis in Its Bacteriological Aspects.—F. H. Thiele and Dennis Embleton give the results of some experiments, which seem to prove that the anaphylactic antibody is identical with the amboceptor. Anaphylaxis can be produced in any animal in which sufficient amboceptor has been developed. It makes no difference how much amboceptor is present, if enough antigen is subsequently given in-
travenously anaphylaxis will result. The idea has been expressed, and is very generally held, that the anaphylactic response is due to a mechanical irritation caused by an alteration in the surface tension. brought about by a precipitation resulting from the interaction of the antibody with the antigen. The authors combat this view, and bring forth evidence to show that alteration in surface tension alone does not cause the symptoms of anaphylaxis. They also show that the antibody, contrary to previous belief, acts as a ferment. The only material objection to this view is found in the contention that the antibody acts quantitatively, but the authors have been able to disprove this idea by providing for the removal of the protein cleavage products by means of dialysis. If the products of the action of the antibody are thus removed the antibody can become free again and is capable of continuing its action without quantitative limit. This ferment action is infinitely rapid in the human or animal body where the optimum conditions prevail, and the very small amount of toxic substance required for symptoms can be liberated almost at once. As to the relation of anaphylaxis to death from bacterial infection, the authors have demonstrated that the blood of such animals contains a sufficient amount of a substance to cause acute anaphylactic death when inoculated into healthy animals, and that this substance is always present, regardless of the infecting organism. Guinea pigs dying from acute bacterial toxemia or septicemia all perish in precisely the same way, with similar symptoms, and uniform pathological post mortem findings. The toxic substance present in their sera is identical, irrespective of the bacterium causing death. The authors, therefore, say: ‘This leads, then, to the conclusion that bacteria have no specific toxic substance, and that the bacterial protoplasm is primarily nontoxic, and becomes toxic only when it has been acted upon by the antibodies present in the infected animal, and the degree of toxicity of a bacterium depends upon the rate of accumulation of these toxic degradation bodies, and this will depend upon the relation between the activity of the antibody present in the animal at the time and the quantity of bacterial protoplasm present—that is, upon the primary dose inoculated and the rate of multiplication of the bacteria. . . . Hence we must not regard this state of so-called anaphylaxis or hypersensitiveness as a freak state, nothing to do with immunity proper, but as a state that can always be made to occur and is relative, depending on the power of the antibody and amount of bacterial protoplasm present; according to the relations between them, acute toxic death, delayed toxic death, or recovery may occur, the toxicity of a bacterium depending upon these factors.”

Action of Asbestos Minerals and Allied Materials on Various Substances.—Myer Coplans, S. A. Edmonds, and W. Gibbs Loyd present three papers in which it is shown that asbestos minerals have a very remarkable absorptive power for a very wide range of substances. These minerals absorb bacterial toxins, proteoses, antitoxins, cobra venom, complements and amboceptors, agglutinins, proteins, pigments, colloids, and diastase from their watery solutions. Many of the substances thus absorbed can be recovered unchanged from the asbestos by suitable methods; others seem to be altered in character. Asbestos also greatly reduces the activity of radioactive solutions, and a portion of the radioactivity is imparted to the asbestos, or can be recovered from it by proper methods. In addition to the substances mentioned, asbestos removes ferments, carbohydrates, alkaloids, and hormones from their solutions or suspensions, more or less completely. Though asbestos has been said to be practically insoluble in water, this is not true, for it is found that on contact with, and in the presence of certain substances particularly, the water shows a progressive increase in its content of electrolytes.

Empusa muscae as a Carrier of Bacteria from the House Fly.—R. M. Buchanan finds by careful experiment, that various pathogenic organisms are not only carried by the fungus, Empusa muscae, on infected flies, but are actually thrown off from the fly by the conidia of the fungus, which are shot off to a distance as great as an inch from the fly. The organisms recovered from a series of flies studied were chiefly of the colon group, an occurrence which is rather to be anticipated from the known habits of the fly. One of the most important facts brought out is that the fungus is probably transmitted from one generation of flies to another by their larve, and it is altogether possible that infective bacteria also may be thus propagated, attached to the fungus.

Proteose-Free Tuberculin.—W. C. Lyons finds that the pure proteose isolated from the culture media used for the preparation of tuberculin will produce a perfectly typical "tuberculin reaction" when applied to the skin of a normal individual. On the other hand, tuberculin from which all of the proteose has been removed will fail to give positive reactions in persons who are normal, and in whom there is no reason for suspecting tuberculosis, while it does react positively in persons known to be tuberculous. This has led Lyons to the study of cutaneous tuberculin reactions with proteose-free tuberculin, and he finds that it is much more valuable as a diagnostic measure than the ordinary tuberculin, not giving reactions in healthy persons. The intensity and duration of the reaction is also of prognostic value. In the early cases the reaction is the most marked, and in the most advanced is the least. Recovering patients give reactions approaching early cases. The proteose-free tuberculin is far less toxic than the ordinary variety and seems to be equally valuable as a therapeutic agent, thus possessing added value.

Lancet.
November 22, 1913.

Primary Cause of Rheumatoid Arthritis.—H. Warren Crowe, in a previous paper, reported the isolation of an organism from the urine of a number of patients suffering from rheumatoid arthritis, and which he named "staphyloft cubus A." In the present communication he seeks to establish the relation of this organism, which he has renamed Micrococcus deformans, to the disease in which it is found so often. Primarily, he has been able
to identify it as being very closely allied to *Micrococcus epidermidis* of Welch, if not actually the same organism. He denotes it *Micrococcus epidermidis*, variety deformans, but has abbreviated the name as already mentioned. By the term rheumatoid arthritis, Crowe means, "only those forms of arthritis which present no demonstrable infection of the joints, and which conform more or less strictly to that typical primary polyarticular disease, sometimes called polyarthritis deformans, characterized by fusiform swelling and redness of the joints, frequently symmetrical in character, usually commencing in the fingers, and associated with glossiness of the skin and muscular degenerations and contractions." Although it has not as yet been possible for Crowe to carry out inoculation experiments with *Micrococcus deformans*, he believes that he is justified by the following evidence in concluding that the organism is the etiological factor of the disease defined above. The organism has been obtained in culture from twenty-two cases; four cases have shown positive complement fixation tests against the coccus; it was found to be the cause of eleven of fourteen less severe and doubtful cases. Opsonic tests in such cases show a typical response to the use of vaccines made from the organism. Agglutination tests also indicate its causative role in these cases. Certain cases of neuritis seem to belong in the same class as those of arthritis, and in these the organism is also found to be the causative agent. In all, forty-eight cases have been examined and the organism has been demonstrated in forty-five, or almost ninety-four per cent. It is also found occasionally in other conditions along with other organisms. All of the tests have been made with adequate controls—normal persons—in whom the tests were uniformly negative. 'Crowe suggests that a neuritis usually precedes the development of the joint lesions in the production of rheumatoid arthritis, and it is in these cases of neuritis that the organism is so constantly present. He believes that the etiological relationship between this organism and rheumatoid arthritis is confirmed by the analogy between the conditions found here and those found in acute rheumatism. The latter has been shown to be due to an organism which is normally present in the human body as a saprophyte—the streptococcus. The same is true of *Micrococcus deformans*, which is normally present on the healthy skin, and only gains entrance to the body in certain cases. Other pathogenic organisms frequently present in cases of rheumatoid arthritis are inconstant, and are in the nature of a secondary infection.

**JOURNAL OF TROPICAL MEDICINE AND HYGIENE.**

**Administration of Quinine in Malaria.**—J. P. Bates designates thirty grains a day as the dose of quinine sufficient in the majority of malarial cases, although in the few cases that tend toward rapid spontaneous recovery three to five grains a day will appear to give satisfactory results. For the therapeutic test the amount is sometimes increased to forty-five grains for one or two days. In cases that pass into the grave and pernicious types, Bates gives from sixty to ninety and even 120 grains a day; these massive amounts are never continued, however, longer than twenty-four hours. In the cases that do not succumb to the infection, the dose is then at once reduced to forty-five grains, and in a day or two more to thirty grains. In the average case, the appearance of full grown, presegmenting and segmenting parasites in the peripheral blood, unusual viscidity of the blood when the ear lobe or finger is punctured, and mental aberrations indicate an increase in the dose to forty-five or sixty grains for a day or two. Absence of these signs, even with large numbers of parasites, indicates a probable average course of the disease, and removes the necessity for doses above thirty grains. In cases where parasites disappear from the circulation, but the gravity of the symptoms increases, quinine is no longer of use and should be rapidly reduced. Bates administers the thirty grain daily doses in two fifteen grain fractions, both in the afternoon; the forty-five and sixty grain doses in three and four fifteen grain fractions, respectively, and larger amounts in ten grain doses every two or three hours. He deems oral administration of quinine more efficacious than hypodermic injection. Where vomiting follows ingestion of the drug, readministration of the latter in ten grain doses after each rejection, with small injections of morphine and hot stimulants, will give satisfactory results. Bates has seen no ill effects from large doses of quinine save temporary ambylopia in a single patient who was taking thirty grains a day. Some patients continued this daily amount by mistake for two or three months, without harm. For the prevention of relapse, Bates advises the taking of thirty grains of quinine daily on three successive days in each week for six or preferably eight weeks.

**Cultivation of Leprosy Bacillus.**—J. M. Santamaria reports observations showing for the first time on an artificial medium the cycle of evolution of Hansen's bacillus from a nonacidfast, filamentary, branching form to an acidfast bacillus.

**Mountain Sickness.**—T. H. Ravenhill reports his experience with this affection in a mining district in Chile, at an altitude of 15,400 to 16,200 feet. Cases illustrating special cardiac and nervous types of the disorder are reported. On the whole, the manifestations vary greatly and are difficult to reconcile. Young, healthy men may be completely overcome, while stout, plethoric individuals of the chronic bronchitis type may not even experience a headache. Some who do not suffer on their first visit may be very ill on their second. Recent alcoholic indulgence and physical exertion increase the susceptibility to an attack. The treatment consists in rest in bed with open windows; light diet, and attention to the bowels. For the headache, acetylsalicylic acid in the dose of one gramme to begin with, then 0.5 gramme every four hours, proved very effective—far more so than acetophenetidin. Oxygen inhalations did not seem to afford relief. In dangerous cases the patient should be promptly moved to lesser altitudes. A certain degree of acclimatization generally takes place at 15,000 feet, which tends to protect the individual when he rises to a still greater altitude; this acclimatization seems usually to be lost, however, after return to sea level for about ten days.
The Use of Bacterial Vaccines in Acute Septic
Conditions of the Oral Cavity Met with by the
Dentist.—Leon S. Medalia says that vaccine treatment is of value in acute septic dentoalveolar abscesses—even the worst types of mandibular impacted third molar abscesses have apparently yielded well to this treatment. Such cases with septic apical abscesses, especially the deep seated ones, or the so called blind abscesses, acute and subacute, have been greatly benefited by the vaccine method of treatment. He believes that there is a big field for this treatment in acute and subacute dentoalveolar abscess cases, and that its widespread use will save considerable suffering and loss of teeth to the patient, and annoyance to the dentist.

The Onomatology of Medicine in Relation to
Its Original Sources.—Samuel Delano presents a strong, scholarly protest against the illiterate, lazy, phonetic spelling that predominates to-day in medical literature throughout the United States. Speaking of the roots of words he justly says: "A root is inviolate. It is struck a mortal blow, if mutilated. It is the badge of ancestry; an indestructible index; an irreducible minimum; it may be neither maul'd, mangled, nor pulverized. As Sidney Smith said of all creatures, classical roots have rights that we are bound to respect." His paper is not a defense of pedantry, but a plea for justice.

Abdominal Adhesions, by R. C. Coffey.—See this Journal for June 28th, p. 1369.

The Production of Ulcer of the Stomach by
Injection of Streptococci.—E. C. Rosenow finds that intravenous injection of streptococci of the proper grade of virulence may be followed by ulcer of stomach and duodenum, the ulceration being due to a localized infection and secondary digestion. He suggests that in the human subject the supposed relation between infected tonsils or gums and gastric ulcer may be due, not to the swallowing of bacteria, as usually believed, but to the entrance into the blood of streptococci, of the kind of virulence to produce a local infection in the wall of the stomach.

Miliary Tuberculosis of the Placenta, with In-
cipient Pulmonary Tuberculosis of the Mother
Becoming Latent after Birth of Child.—A. S. Warthin shows, that even in the case of an unrecognized latent lesion in the lung of a pregnant woman, tubercle bacilli may enter the circulation and produce a miliary placental tuberculosis. If this is possible it is also possible that, under such circumstances, the bacilli may pass the placenta and enter the body of the fetus. The case also emphasizes the point which the author has made in previous papers, that there is apparently some especial resistance on the part of fetal tissues to the tubercle bacillus, since tubercle bacilli have been found in large numbers in the liver and blood of infants without any histological appearances of tuberculosis. The low virulence of the placental infection in this case may possibly be explained, he says, as the result of such a relative immunity on the part of the placental tissues.

Myotonia atrophica.—Foster Kennedy reports a case of this peculiar muscular degeneration and states that myotonia congenita, or so called Thom-
sen's disease, is not very uncommon, but the combi-
nation of increased tonus in some muscles with a primary flaccid palsy in others, in remarkably con-
stant distribution, is so rare that but four cases have as yet been reported in the medical literature of this country.

Polyposis gastrica (Polyadenoma).—J. S. Meyer, who reports a case of polyposis gastrica, states that as far as he is able to learn, there has been but one other case, that of Chosrojeff, in which a diagnosis was possible prior to operation or necropsy. His conclusions are: 1. Though the diag-
nosis was made possible in this case through the presence of a small polyp in the wash water during lavage and the presence of a large polyp in the feces following a hemorrhage, it would seem that at least a probable diagnosis might be made in future cases without this conclusive finding. 2. The röntgeno-
graphic and fluoroscopic examinations in a case as extensive as this should always be helpful. 3. Aehyllia gastrica, together with unusual mucous produc-
tion, should arouse suspicion. 4. The repeated pres-
ence of fresh blood microscopically in gastric con-
tents removed with care is indicative of a redundant, vulnerable condition of the mucosa in which bits of tissue are readily removed by the tube. 5. In severe acute gastric hemorrhage in a patient with aehyllia gastrica, abnormal mucous production, and normal or increased gastric motility, polyposis is more than probable. 6. Invagination of the pylorus by a polyp could hardly be mistaken for any other condition, after one has experienced the peculiar palpatory findings met with in this case. 7. The etiology is very obscure, but it would seem probable that syphilitic gastritis was here the underlying cause.

A New Operative Treatment for Spastic
Paralysis—Preliminary Report.—W. Sharpe and
B. P. Farrell give reports of two cases and state that in instances of spastic paralysis of the hemi-
plegic, paraplegic, or diplegic type, with a definite history of difficult labor with or without the use of instruments, in which, on ophthalmoscopic examination, signs of intracranial pressure are shown in the distal retinal veins and a blurring of the optic discs, especially of their nasal halves, a large right subtemporal decompression is performed to relieve the intracranial pressure. If the intracranial pres-
ure is extremely high, and remains high after op-
eration, a left subtemporal decompression is per-
formed the following month. The method of deal-
ing with the various pathological lesions found at operation will be discussed in detail in the more complete report to be published later. The after-
treatment consists in the correction of deformities by tendon stretching, the maintenance of corrected positions by means of braces, and skilled massage in conjunction with muscle training and short applica-
tions of galvanism and faradism.

in dreams and neurosis as fanciful and far-fetched, and who deny the importance of sexuality in nervous disorders, he would say that if they will only apply Freud's method of letting the patients tell all the thoughts which come to their minds, and without being discouraged the first time a subject says, "I can't think of anything more, Doctor," persist for a reasonable length of time, they will surely have ample reason to cease doubting and denying the things mentioned; though without some technical knowledge they are not likely to effect any cures.

The Mechanism of Immunity in Experimental Cancer.—From the researches of others and personal experimentation on animals I. Levin concludes that the condition of immunity in experimental cancer, while not identical with, is very similar to the immunity in bacterial diseases, and is due to an active inhibitory influence of the organisms of the host upon the proliferative power of the cancer cells. Furthermore, such an inhibitory action may be produced locally by a certain organ in a generally susceptible animal. As regards cancer in man the author accordingly believes that it is of the greatest importance to study the conditions of organ susceptibility or immunity. Not only will it be possible to learn ultimately in this manner the true pathogenesis of the disease, but also to find the correct methods for its prevention and treatment. It is possible to suppose, for instance, that the action of chemotherapeutic measures or of the radioactive substances is due not only to their deleterious effects upon the cancer cells, but also to the purely local increase of the inhibitory action of the normal organ tissue surrounding the growing tumor.

Results of Treatment of Syphilis with Salvarsan and Neosalvarsan.—S. H. Wadhams and E. C. Hill, of the Medical Corps, U. S. Army, report the following conclusions from their experience in the military service: 1. Salvarsan and neosalvarsan, given intravenously, do not appear to cure syphilis. 2. They are of very great value in the active stages of the disease, and are especially useful in patients who cannot tolerate mercury. 3. No harmful results have been noted from frequent injections. 4. No patient should be allowed to assume that he is cured after one or more injections unless the Wassermann reactions, taken at definite intervals for a year or more, are continually negative and the patient has abstained from alcohol for forty-eight hours previous to the test.

Benign Tumors of the Female Breast; Report of a Case.—In the case reported a radical operation was performed, and the author, W. E. Hartshorn, states that in the differential diagnosis of benign tumors of the breast the following types must be considered: Periductal fibromatosis, periductal myxomata, cystadenomata, and inflammatory types. The type depends upon the proportion of fibrous tissue or epithelial cells present, and they constantly merge one into another. Regarding the danger of the tumor, a safe statement would be that the greater the proportion of the epithelial element, the greater the possibility of a serious outcome. Benign tumors of the breast are best treated by complete excision, this term being used to include removal of the breast. It is not necessary always to do a radical operation, but in all doubtful cases the rule should be, complete excision, removal of the muscles, and a dissection of the axilla. It is far wiser to be too radical than to risk the blame sure to follow a recurrence. Each case must be weighed as a clinical entity to be decided by itself; no general rule can be safely laid down. Occasionally a transverse incision along the lower border of the breast will be found advisable.

ARCHIVES OF INTERNAL MEDICINE.

October, 1913.

Absorption of Protein without Digestion.—E. Van Ness Van Alstyne based her studies of this question on the fact that no method compares with the observation of the presence or absence of an anaphylactic reaction as a means of sharply distinguishing closely allied proteins. The experiments reported showed that protein may be absorbed unaltered through the intact epithelium of the gastrointestinal tract. While physiologically the amount thus absorbed is too small to be of significance as a factor in nutrition, conditions interfering with normal digestive function, such as ligaturing a portion of the intestine, or the whole stomach, or isolating part of the intestine as a fistula, markedly increase this amount, exception being made, however, for the duodenum, ligation of which does not facilitate absorption of unaltered protein. The amount physiologically absorbed, though small, may be of decided import, in that only a very small quantity of protein is required to sensitize an animal or intoxicate an already sensitized animal. These observations would seem to be of significance in the explanation of asthma through anaphylaxis, of many skin conditions classed by dermatologists as anaphylactic in nature, and of certain food intoxications.

Relation of Fatigue to Localization of Paralysis in Plumbism.—R. R. Mellon reports experiments upon frogs, proving conclusively the validity of Edinger's contention, that lead in itself has no predilection for any group of muscles except as such choice is made possible by their overuse. Fatigue is, therefore, the main factor in the localization of lead palsies. Some evidence to this effect has already been obtained clinically.

Reinspiration of Expired Air.—T. R. Crowder found samples of air taken from within the nostrils during inspiration to show an excess of carbon dioxide over that in the air of the room in general, and from this excess calculated the propor-
tion of expired air reinspired. When remaining quiet indoors, a person rebreathes from one to two per cent. of this air, and when in bed, from one to five or even ten per cent., according to the position assumed. By means of artificial air currents reinspiration can be prevented entirely, provided the face is free to receive the current. Sleeping in tents, tent houses, or half open porches does not obviate it. Reinspiration to a moderate extent cannot be considered harmful, since in healthy persons, rebreathing carbon dioxide automatically causes a compensatory increase in pulmonary ventilation, which will serve not only to reduce the carbon dioxide in the air cells, but also any toxic protein or other organic substance that may be present. The author holds it an error to suppose that the good effects of efficient ventilation are due to greater chemical purity of the air; the respiratory function being—normally at least—perfectly adapted to maintain its balance through a wide range of chemical purity. Ventilation is essential rather in the interest of the heat economy of the body. Metabolism being reflexly retarded by a warm aerial envelope, ventilation is necessary in order to maintain the thermic balance of the body and to stimulate its chemical activity; ventilation with cool air is especially desirable.

**Functional Kidney Testing in Uremia.**—N. B. Foster refers to three cases of chronic nephritis, with diagnosis confirmed at necropsy, in each of which the phenolsulphonephthalein test had given a result approximating the normal, in spite of the subsequent early fatal termination. In one of these cases the test was made only four days before death, and in another, eleven days. The author points out that it will be necessary to ascertain in what proportion of cases of renal disease one is apt to be thus misled before forming an opinion as to the diagnostic or prognostic value of the test.

**Blood Pressure in Tuberculosis at a Great Altitude.**—L. S. Peters and E. S. Bullock conclude from a study of this question in six hundred cases, that the blood pressure of both normal individuals and consumptives is higher at 6,000 feet than at sea level. The pressure tends to increase, up to certain limits, with continued residence. From a prognostic standpoint the blood pressure findings are of great value in tuberculosis. There is no relation between the degree of involvement and blood pressure, but there is a constant relation between the degree of toxemia and blood pressure; the latter being, on an average, increased in patients with a temperature of 99° to 100° F., and lowered in those with temperature above 100° F.

**INTERSTATE MEDICAL JOURNAL.**

October, 1913.

**Eradication of Malaria.**—C. C. Bass expresses the opinion that all that is required for the complete eradication of malaria is for every one who had malaria during a warm season to take the proper amount of quinine on each of two successive days in each of six consecutive weeks during the cool season following. If this statement could be brought with sufficient authority to the attention of all the people, and if the importance of everybody's cooperating could be emphasized, he believes that a vast majority of the malaria carriers would follow the advice given. In spite of the most thorough dissemination of this information, no doubt a few cases of malaria would occur during the warm season, but these cases are not a source of infection to mosquitoes until the disease has lasted about two weeks, and it is very important that thorough and successful treatment should be applied before they become infectious. Eradication of malaria becomes, in fact, therefore, a question of educating the people. Effort to secure eradication along educational lines would meet with two serious obstacles. First, there would be a few infected persons who would not follow the advice given, either because they think they know more about the disease than the scientists who have studied it for many years, or because they have not enough concern for the health and life of themselves and others to take proper treatment. The question would arise, the author says, whether such people should not be segregated until they are no longer a menace to the community. The second important obstacle would be the importation of cases of malaria from other countries, and in the event of our getting sufficiently free from the disease here, there would be the same reason for preventing others from bringing this infection into the country as there is for quarantine regulation to prevent the introduction of yellow fever, trachoma, etc. As a further protection it might be possible to carry the propaganda of education into various tropical countries, and thus materially assist them to check the ravages of the disease.

**Medical Inspection and the Nutrition of School Children.**—I. S. Wile states that the relation between nutrition and medical inspection is patent. The inspection should be so thorough as to indicate not merely the names of various symptoms and conditions, but should suggest whether or not malnutrition could possibly be an underlying factor. Under such conditions school lunches could serve in a remedial way by raising the standard of nutrition. Frequently the inspections reveal some children not possessing marked defects, but who are very close to the health poverty line, and for them school lunches could be instituted for prophylactic purposes. Most civilized countries have already installed such lunches as a natural and normal part of an educational movement, without laying unnecessary stress upon its value as a health measure. As medical inspections are regarded as advantageous to the school system through the lessening of disease and the improvement of the mental calibre of the children, careful attention to nutrition may supply a valuable means of increasing mental activity and building up the physical health of school children.

**ANNALS OF OPHTHALMOLOGY.**

October, 1913.

**New Operation for Extirpation of Tarsus of Upper Lid; Report of a Case.**—F. W. Dean reports a case in which he removed the tarsus through an incision through the skin surface of the lid, instead of through the conjunctiva, as in Kuhnt's operation.
CLINICAL CONGRESS OF SURGEONS OF NORTH AMERICA.

George Emerson Brewer, President.

(Continued from page 1138.)

Some Uses of Fat in Surgery.—Dr. John F. Binnie, of Kansas City, said that fat was well suited for transplantation in many instances. It was undoubtedly the connective tissue, the basis of the fat, which was of value in the transplant, but in other instances other varieties of connective tissue would be valueless compared to that which was infiltrated with oil. The control of hemorrhage was difficult to obtain in wounds of the liver. Tampons of foreign material, while useful, had obvious objections. The sutures were liable to tear out in the friable tissues. Such wounds might be treated by omental grafts. The omental plug became adherent to the raw surface of the liver wound, prevented hemorrhage and became converted into fibrous tissue. A number of liver wounds had been successfully treated by omental tamponade. Doctor Binnie related numerous cases in which fat had been, and could be used to great advantage as a transplant.

Peridental Infections: Their Relation to Neighboring Organs.—Dr. V. P. Blair, of St. Louis, stated that it was now recognized that the clinical manifestations of disease that we classify were in most cases the direct or indirect results of infections that gained entrance to, or were harbored in some particular organ or part of the body. The appendix, the urethra, the kidneys, the skin, and the tonsils had been recognized as important primary or intermediary foci of infection. But while the mouth was the most prolific of all, it was only lately that oral sepsis began to receive the attention that it deserved. Exclusive of the tonsils it was the teeth and their immediate coverings that here furnished the great atra of infection that menaced every tissue and structure in the body.

Pyorrhea alveolaris in an advanced form was not a common affection, while dental caries was the most common afflication of the civilized races, hardly five per cent. being exempt. After caries had penetrated into the pulp chambers there was an open avenue to the vascular tissues about the apex of the teeth and thence through the blood and lymph streams, and possibly the nerves, to all of the body tissues. Pathogenic organisms lodged and incubating within the pulp chamber and root canal might thus be disseminated.

The proportion of antral empyemas that were attributed to dental infections was variously estimated up to fifty per cent. Based upon observations made during eighteen years as demonstrator of anatomy in the dissecting room, it was his belief that infection of the antral mucosa of dental origin was rather rare, but that infection and suppuration in the submucosa was exceedingly common. They had observed two cases of torticolis with early scoliosis that were relieved by opening an alveolar abscess in each. Of nine cases of Ludwig’s angina which had been seen, four were due to dental sepsis.

The purely local effects of peridental infection were not always of a chronic character. They might be extremely acute and very extensive, going to an acute alveolar abscess, a necrosis, cellulitis, or adenitis. They had seen three cases of sarcoma or malignant endothelioma and one of Hodgkin’s disease beginning in the cervical lymphatics. Two forms of cellulitis of the neck were worthy of special mention; one, the chronic Hollephlegmon, three cases of which he had observed to be of dental origin, and the so called Ludwig’s angina, to which latter when not promptly and properly treated in the past had been ascribed a death rate of forty per cent. Hugo Stark had found in 113 children with chronically enlarged cervical lymph nodes that eighty per cent. had carious teeth and in forty-one per cent. of this eighty per cent. no other cause, not even hereditary, could account for the lymphangitis. In a few cases of tuberculous adenitis the tubercle bacillus was found in a curious tooth corresponding to the infected node. It was now recognized that the so called metastatic or secondary parotiditis was directly dependent on oral sepsis traveling up the excretory duct, and they had been able to express pus from Stenson’s ducts before any suppuration was evident in the glands.

Premature loss of the teeth might change the shape of the jaws and secondarily the nasal chambers. Irregular eruption had been cited as a cause of nasal spurs and deviation of the septum. One hundred and ninety-seven cases of ankylosis of the jaw were reported in the literature; in only five cases was infection of the teeth given as a cause. In twelve cases of their own two more were due to scar bands in the cheek due to intraoral slough, but a dental origin of the sloughing was not certain. Like any other joint the temporomandibular might be indirectly affected by chronic suppuration in any part of the body. The view that baldness might be dependent upon dental disorders was strongly supported by French writers.

Among the most interesting were the sensory, mental, and physical derangements that might be due to dental abnormalities. In ninety-four cases of tic douloureux which they had examined, dental irritation was the apparent cause in twenty-six, but thirty-five out of the ninety-four began in the third division of the nerve. Trommer observed that in fifty-eight cases of mental derangement thirty showed impacted teeth, and that in twenty-two of twenty-eight cases of mental derangement operated in, definite improvement had taken place within two weeks after operation. They had also observed similar instances, and in examining cases of epilepsy that were sent to them for operation they paid particular attention to the condition of the teeth.

The Surgery of the Fauclal Tonsil as It Relates to the Functions of the Tongue and Soft Palate in the Production of Voice.—Dr. G. Hudson Makuen, of Philadelphia, stated that the faucial tonsil differed from other tonsils, not only in respect to the conditions attendant upon its location in the pharynx, but also in respect to its development. The faucial tonsil was not a homogeneous, but a complex organ, and it was more
highly specialized than the other tonsils which combined to form the so called Waldeyer's ring. In addition to the possible systemic functions of the tonsil during childhood, it had during adult life certain important mechanical functions which were chiefly operative in phonation and articulation, and even in old age after it had undergone what had been called physiological sclerosis, its mechanical functions continued, and the tonsil then served as a protective agent to the faucial region in that it built up and strengthened that portion of the intrapharyngeal aponeurosis known as the capsule of the tonsil by the addition of its own connective tissue. The capsule of the tonsil was even more essential to the maintenance of the normal structural relations of the pharynx than the tonsil itself, and its removal was to be deprecated from the standpoint of one who had any regard for the phonatory and articulatory functions of the adjacent muscles. The mechanical functions of the tonsil in phonation and articulation were threefold: First, it served to maintain the normal anatomical relations of the soft palate, the tongue, and the larynx; second, it served to keep the pillars of the palate apart and to direct them in their phonatory and articulatory activities; and third, it had in itself important acoustic properties in artistic vocalization.

An extracapsular tonsillectomy required a more or less extensive dissection of the mucous membrane covering the tonsil, the important muscles adjacent to the tonsil, a large portion of the intrapharyngeal musculoaponeurotic sheath, and in some instances also a portion of the peripharyngeal aponeurotic sheath.

This extensive dissection resulted in a large granulating cavity in which union took place between the cut or lacerated surface of the mucous membrane, muscles, and musculoaponeurotic sheath or sheaths, binding them all together at central points of cicatrization, and several months after the operation the old landmarks that formerly characterized the distinctive features of the walls of the pharynx were practically gone forever. Instead of the beautiful clean cut sharp edges of the palatal pillars during phonation and articulation and the well marked pharyngeal recesses both between and on either side of the pillars, they had plain oval pharyngeal walls with occasional bands of tense fibrous tissue coming into greater prominence when the mouth was open and the tongue depressed. Moreover, the normal mucous membrane of the parts having been destroyed, its place was occupied by smooth cicatricial tissue having a glistening surface and no mucous secretion whatsoever.

The three important peripheral organs of phonation and articulation, viz., the soft palate, the tongue, and the larynx, were anatomically and physiologically interdependent, and possessed many points of similarity. The integrity of the soft palate was essential to the distinctive structural characteristics of the pharynx and to the normal action of the tongue and larynx. The palatopharyngeus muscle, owing to its direct connection with the larynx, had important cord stretching functions, and the valvular action of the soft palate in phonation and articulation was well known. Radical surgery of the tonsils must necessarily result in a greater or less distortion of the pharyngeal structures and, therefore, in an injury to the voice. The normal tonsil or the one in a healthy condition and of normal or approximately normal dimensions was not only beneficial to the voice, but it was absolutely essential to the attainment of the highest artistic results in singing and speaking, but just as the normal tonsil was helpful in voice production the abnormal tonsil might be altogether prejudicial, and it might be prejudicial to such an extent as to make some kind of tonsillar surgery absolutely imperative. Before doing radical tonsillar surgery it seemed only reasonable to demand a thorough differential diagnosis. It was easier to enucleate than it was to investigate, and especially was this true with their improved technic, in the perfection of which they had spent so much valuable time. Future years would find them trying, not how to enucleate, but how to avoid enucleation.

The extracapsular tonsillectomized pharynx was always necessarily a damaged pharynx, and the operation ought to be done only when absolutely necessary, and when the damage to the pharynx and to the individual threatened to become greater by leaving it undone. In the majority of instances the only good reason for doing an extracapsular tonsillectomy was the difficulty of doing an intracapsular tonsillectomy, which consisted in a careful dissection of the gland from within its pocket in the intrapharyngeal aponeurosis. This was a difficult but not impossible operation, and the fact that some tonsillar tissue might remain adherent to the capsule was no objection to it because when the operation was properly performed good drainage, the sine qua non of every operation, would be thoroughly established.

Operations on the Extraocular Muscles.—Dr. Edward Jackson, of Denver, said that operations on these muscles had had periods of great popularity and almost complete disuse, because of failure to apply well known facts of physiology to the ocular movements. Most movements required the cooperation of all the muscles; and the operation on one muscle changed the balance for all movements.

Tenotomy of the internal rectus and external rectus was liable to leave the position of the eye in control of the secondary adductor muscles—the superior and inferior recti, or the secondary abductor muscles—the obliques. Contraction of the secondary adductors had as much effect in producing convergent squint as contraction of the internal rectus. Hence tenotomy should be extended to the nasal margins of the tendons of the superior and inferior recti.

The vertical movements were intimately associated with wheel rotation of the eye. Paralysis of the superior obliques was to be corrected by transplanting the insertion of the superior rectus back and out, so that it would have more power to cause wheel rotation with less power to turn the eye up. By changing the insertion of a muscle upon the eyeball its function could be radically altered.
Tumor of the Spinal Cord.—Dr. H. Climenko reported two such cases, and showed the specimens. The first case, which he said was an instance where syphilis could mask the diagnosis of a tumor of the cord, was that of a married woman, a Jewess, fifty-five years old; a native of Austria. When she was admitted to the Montefiore Home, on November 17, 1911, she stated that both of her parents had died in the forties, her mother of some wasting disease of many years' duration. One brother died of cardiac disease. There was no history of miscarriages in the family. Her personal history was that she was the youngest child, breast fed; that she had convulsions in early childhood and was always of a weak and delicate constitution. Her menstrual history was negative. She married at the age of twenty-one; she was the mother of nine healthy children and had never miscarried. About four years after her marriage she was treated for cystitis, and ten years ago she had a superficial ulceration of the left leg. Her present illness, dating back about fifteen months, was insidious and progressive. She first suffered from numbness and tingling and tugging sensations, commencing in the soles of both feet and gradually extending up to the hips. Shortly afterward pains developed in the region of the midspine radiating downward into both legs. These were more or less constant. Following these, there was weakness and stiffness in both legs which was preceded by a girdle sensation in the lower abdomen. About three months later she lost the power to walk, and two months prior to her admission incontinence of both the urine and feces developed. A few weeks ago, she noticed tingling sensations in the little finger of the right hand. There was no history of diplopia, headaches, vomiting, or convulsions. When Doctor Climenko first saw the patient, at the time of her admission to the home, she could neither stand nor walk. She lay on her back and could sit up only with difficulty. Both lower extremities were flexed and extremely spastic. The double Babinski, Oppenheim, Mendel, and Bechtereff reflexes were present. There was double ankle clonus and both knee jerks were very lively. The lower abdominal reflexes were absent. The various reflexes of the upper extremities were present and normal; the pupils reacted to light, accommodation, pain, and consensually. The gross motor power of the active movements in the lower extremities was greatly diminished and carried out very sluggishly. The passive movements were difficult to carry out, due to the enormous spasticity. The spine did not show any deformities, but there was marked hypersonsibility to pressure over the tenth, eleventh, and twelfth dorsal spines. The cranial nerves were negative. There were marked sensory disturbances, extending from the mammary downward anteriorly and posteriorly. An examination of the blood gave a positive reaction to the Wassermann test. The cerebrospinal fluid was negative, but showed an increase of globulin. The patient was given two full doses of salvarsan and many intramuscular bichloride injections, after which her condition was slightly improved. On May 20, 1912, after a careful study of the sensory disturbances, and influenced by the marked spinal tenderness, a diagnosis was made of a constant lesion within the spinal canal, causing pressure on the cord. The patient was operated on by Dr. Charles A. Elsberg on June 14, 1912, when he removed an elliptical, cauliflowerike tumor, situated at the level of the ninth, tenth, and eleventh dorsal vertebrae, and measuring three quarters by one half by one quarter inch. Pathologically, this proved to be an endothelioma.

The second case reported by Doctor Climenko was that of a widow, fifty-two years old, born in Russia of Jewish parents, who entered the Montefiore Home on March 21, 1913. In her case the symptoms, which pointed to a lesion in the upper segment of the cord, were such that an operation could not be considered. She died on July 6, 1913, and the autopsy showed a tumor in the cervical region, the cord here being enlarged throughout the entire length to about twice its normal thickness. Pathologically, the lesion was a glosarcoma, with resulting degeneration of the cord.

A case of Manic Depressive Psychosis in a Child.—Dr. M. S. Gregory presented a girl, ten years old, who was born in Austria and came to this country with her parents about three months ago. No history of a psychosis or a neurotic taint in the family or its collateral branches was obtainable. The patient was the third of four children, two of whom died in infancy. Her childhood was apparently normal, and during that period she had the usual diseases, without complications or sequelae. She was considered an average scholar, and her deportment showed no abnormality. She was bright and cheerful, took an active interest in play and associated with children of her own age. She was easily angered, however, and excited, and unduly sensitive. She was an only daughter. The child's parents stated that she was perfectly well until the early part of August, 1913, when she experienced, a great disappointment because her mother would not permit her to go to a party. On the following day she was unusually quiet and sad. She complained of headache and refused food. She insisted that she was weak and had a pain in the cardiac region. She would remain seated in one place without showing much interest. On August 24, 1913, when she was brought to Bellevue Hospital, a physical examination revealed no objective evidence of a neurological disorder. The pupils responded to light and accommodation; the optic discs were normal. The knee jerks were active and there were no sensory disturbances nor hysterical stigmata. Mentally, she was profoundly depressed and remained in the characteristic attitude of flexion, with head bowed and body bent forward. Her general movements were slow and delayed. She said nothing spontaneously; answered a few questions to the point, but in a rather low tone of voice and after some deliberation. She complied with the usual requests, although slowly. When asked what ailed her she complained of headache and pain in the stomach; said that she could not walk and wished to go home. She would calculate slowly.
and occasionally, when she made mistakes and her attention was called to them, she would rectify them. She was well oriented and gave a good account of herself, memory for both remote and recent events being good. There were no hallucinations nor delusions. In the ward she would sit quietly by herself, manifesting no initiative. She took food when it was given to her, but never asked for anything nor expressed any desire. She seemed to be in touch with her surroundings, however, and apparently took notice of what was going on about her. She remained in this condition for several days, but gradually improved, so that on September 13th, about three weeks after admission, she was taken home contrary to medical advice. Her mother stated that when she returned home she was in fairly good condition for a few days, but that her depression soon returned. She was readmitted to the hospital a week later in a condition much the same as that on her first admission. However, she soon began to improve and at the present time she was fairly active, smiled occasionally, spent her time in playing with picture blocks and puzzles, and took outdoor exercise, but she was still quiet and was rather slow in her movements. She did not talk spontaneously, but when addressed she smiled and answered questions in a low tone of voice. She said she now felt well and was anxious to go home. The Binet-Simon test showed her scale of intelligence equal to nine and a half years of age. Manic depressive psychosis, Doctor Gregory said, was apparently very infrequent in childhood. At least, the literature was very meagre. It was possible that the disease was more frequent than suspected and that such cases were often unrecognized and mistaken for other disorders. Very often the depression might be associated by the parents and even by the family physician with the bodily condition of the child, and these cases naturally rarely came to the attention of the psychiatrist. During the past eleven years, the speaker said, he had seen only four cases under the age of twelve years. Manic depressive attacks, however, occurring between the ages of twelve and fifteen were comparatively frequent. The youngest of his four cases was a girl of seven, who had the manic phase of the disease, which lasted six weeks and ended in recovery. In another, a boy of eleven, the disease followed a severe fall. He had alternate attacks of depression and excitement, each lasting a week. He recovered in five weeks. The third, a boy of twelve, manifested an attack of excitement of two weeks' duration, with complete recovery. It was of interest to note that in all of the cases mentioned the attacks were of rather short duration, which coincided with the observations of Ziehen and others.

Doctor Jelliffe, the president, said that so far as his review of the records showed, this was the first case of manic depressive psychosis in a child of ten years that had ever been presented or reported at a meeting of this society. He agreed with Doctor Gregory that such cases might readily be overlooked by the parents or physician, and that the symptoms might be attributed to malaria, constipation, or various other bodily ailments.

(To be continued.)
that the section of the total bacterial flora which is obtained should be thoroughly representative of that portion of it in which we are most interested—the group are quickly growing, rich-food-loving, sewage forms. Warning is given that agglutination tests for the typhoid bacillus are not significant unless obtained in dilutions as great as one in 500 or one in 1,000 particularly on account of its close relationship to Bacterium subtilium. This organism is a valuable one and should be in the possession of all who are doing work connected with the bacteriology of water.

The author shows very well how important the Röntgen rays can be in the diagnosis of intestinal diseases. In the brief mention of the technic recommended the use of barium sulphuricum purissimum is advised. By the aid of illustration the various positions of the normal intestines are indicated clearly. Subsequent chapters take up the questions of chronic functional obstruction, ulcera, and strictures of the intestine; the different conditions being well shown by x ray pictures.

By omitting illustrations and mooting methods Doctor Abel has made this little book a valuable one for actual laboratory work, as it is, in fact, a presentation of the most important methods employed in carrying out bacteriological examinations. Much is added to the usefulness of the book by its being intercalated. That its value has been appreciated is evidenced by the fact that this is the seventeenth edition.

Interclinical Notes.

Dr. Ben Trovato informs us, that in reply to a young colleague specializing in diseases of the chest, who wrote to him asking what would be a suitable present for his fiancée, he has suggested a necklace composed of alternate settings of Lannec pearls and Chacot crystals. According to the doctor, any asthmatic jeweller in the lapidary could supply unlimited quantities of these gems.

Sir Almroth E. Wright in The Unexpiated Case against Woman Suffrage, besides many inaccuracies of his own, suffers from two by his publisher (Paul B. Hoeber, New York; $1 net), who misspells his name on the cover and gives also a variant of the title of the book. The work is so partial and so venomous in its attack on women that it will afford amusement even to ardent and prejudiced women. Sir Almroth will not admit that women have a single claim on the vote, nor does he seem to allow that not every man is wise in his exercise of the suffrage. He insists also that every woman get married despite the difficulties in the way, not the least of which is the discrepancy in numbers compared with men. Of such questions as child labor, he makes light, averring that they can be easily settled by "a little good will." Sir Almroth furthermore ignores such well known phenomena as wife beating when he only says that "the reign of force which prevails in the world comes to an end when a man enters his household." Does he never read the papers? Many a woman could tell him that physical violence would be preferable to some things she has to suffer under the present regime; yet even Sir Almroth blandly says matrimony "this is the covenant so faithfully kept by man." We do not hold a brief for woman suffrage and do not profess to know how it would work out. We are sure, however, that a book of this kind will make no converts, for despite the fact that some of Sir Almroth's contentions are correct, they are presented in so unfair and intemperate a style that his arguments, like vauling ambition, o'erleap themselves and fall on the other side. If women, indeed, are the extraordinary creatures the distinguished author says they are, it is high time they were deprived of the privilege of supervising the early education of men, for the opportunities they possess of inculcating their erroneous views on the mind during the first impressionable decade of its existence are enormous, and a natural lack of cooperation on the part of the men has been attributed to them by Sir Almroth—furnish a most unfortunate example to their young charges.

Meetings of Local Medical Societies.

Tuesday, December 16th. New York Academy of Medicine (Section in Ophthalmology); Medical Association of the Greater City of New York; Medical Society of the County of Erie (annual); Elmira Clinical Society (annual); Hartford, Conn., Medical Society.

Tuesday, December 16th. New York Academy of Medicine (Section in Medicine); Psychiatric Society of Ward's Island; Tri-Professional Medical Society of New York; Medical Society of the County of Kings; Buffalo Academy of Medicine; Binghamton Academy of Medicine; Clinical Society of the Elizabeth, N. J.; General Hospital, Syracuse Academy of Medicine; Ogdensburg Medical Association; Oswego Academy of Medicine.

Wednesday, December 17th. New York Academy of Medicine (Section in Genito-urinary Diseases); Woman's Medical Association of New York City (Academy of Medicine); Medical Society of the County of Kings; Buffalo Medical Club; New Jersey Academy of Medicine (Jersey City); New Haven, Conn., Medical Association.

Thursday, December 18th. New York Academy of Medicine (stated meeting); German Medical Society, Brooklyn; Aesculapian Club of Buffalo; Newark, N. J., Medical and Surgical Society.

Friday, December 19th. New York Academy of Medicine (Section in Orthopedic Surgery); Clinical Society of the New York Postgraduate Medical School and Hospital; New York Microsopical Society; Brooklyn Medical Society; Alumni Association of Roosevelt Hospital; Saratoga Springs Medical Society.

Official News.

United States Public Health Service:

Official notice of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending December 3, 1913:

Goldberger, Joseph, Surgeon. Directed to proceed immediately to Detroit, Mich., for an investigation of an outbreak of diphtheria, and to advise with the local health authorities regarding the measures necessary to control the epidemic. Kearny, R. A., Assistant Surgeon. Directed to report to the Division of Domestic (Interstate) Quarantine for duty in the inspection of public buildings in Washington, D. C. Liddell, T. J., Assistant Surgeon. Directed to proceed at such time as may be practicable, to various places in Louisiana to obtain data and material for determining the incidence of malaria. Oakley, J. H., Surgeon. Directed to proceed to Louisville to cooperate with the local authorities, make an investigation of the prevalence of trachoma in the schools of Jefferson County, Ky., Smith, F. C., Passed Assistant Surgeon. Authorized, together with necessary witnesses, to proceed to El Paso, Texas, for the purpose of testifying for the government in water right's case. Warren, B. S., Surgeon. Upon the request of the chairman of the United States Commission on Industrial Relations, and with the approval of the commissioner, detailed for duty with that commission for the investigation of industrial sanitation and hygiene.
Board Convened.

Board of commissioned medical officers convened to meet at the Bureau, Monday, December 1, 1913, at 10 o'clock a. m., for the purpose of examining Assistant Surgeons Robert L. Wilson and John T. Burkhalter, to determine their fitness for promotion to the grade of surgeon. Detail for the board: Assistant Surgeon General W. Simpson, chairman; Assistant Surgeon General W. C. Rucker, member; Surgeon J. W. Schereschewsky, recorder.

United States Army Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Army for the week ending December 6, 1913:

Bartlett, W. K., Captain, Medical Corps. Ordered to Fort Huachuca, Ariz., and thence to accompany the Second Cavalry to Fort Ethan Allen, Vt.

Brooke, W. S., First Lieutenant, Medical Reserve Corps. Ordered to temporary duty at Fort Dade, Fla., and thence home where he will be relieved from active duty in the Medical Reserve Corps, at the expiration of the leave of absence for one month and twenty-six days, which has been granted him from duty at Fort McKinley, Maine, and after being granted all the leave of absence due him, will proceed to his home standing relieved from active duty.

Kramer, Floyd, Captain, Medical Corps. Relieved from duty in the Army Transport Service and will proceed to Fort McKinley, Maine, for duty.

Mayo, Harry N., First Lieutenant, Medical Reserve Corps. Ordered to active duty and assigned duty at Fort Douglas, Utah, for duty.

Wilson, J. S., Major, Medical Corps. Ordered to Fort Huachuca, Ariz., and thence to accompany the Second Cavalry to Fort Ethan Allen, Vt.

United States Navy Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Navy for the week ending November 29, 1913:

Backus, J. W., Surgeon, Medical Corps. Detached from the South Dakota and ordered to the Navy Yard, Puget Sound, Wash.

Hoen, W. S., Passed Assistant Surgeon, Medical Corps. Detached from the Navy Yard, Mare Island, Cal.

Kelley, H. L., Passed Assistant Surgeon, Medical Corps. Detached from the North Carolina and ordered to the Prairie.

McLean, N. T., Passed Assistant Surgeon, Medical Corps. Detached from the Navy Yard, Mare Island, Cal., and ordered to the Asiatic Station.

Steeple, Jacob, Surgeon, Medical Corps. Detached from the Montana and ordered to the Prairie.

Births, Marriages, and Deaths.

Married.

Baum—Lawrence.—In New York, on Monday, November 24th, Dr. Wilhelm Ludwig Baum, of Chicago, and Mrs. Dwight Lawrence. Bockar—Baff.—In New York, on Thursday, November 27th, Dr. Aaron Bockar and Miss Jeanette Baff. Darrah—Hand.—In Chicago, on Tuesday, November 25th, Dr. Leo C. Darrah, of Reading, Pa., and Miss Helen L. Hand. Hartford—Carroll.—In Philadelphia, on Monday, November 24th, Dr. Albert F. Hardt and Mrs. Louise H. Carroll.

Lanza—Theodore.—In New York, on Tuesday, November 18th, Dr. Anthony Lanza, of the United States Public Health Service, and Miss Laura Kate Thomas. McCall—Barnes.—In Connellsville, Pa., on Monday, November 24th, Dr. John C. McCall and Miss Ina C. Bowman. Newman—King.—In Elizabeth, N. J., on Wednesday, November 26th, Dr. Louis G. Newman, of Westfield, and Miss Gertrude King. Died.

Boyer.—In Philadelphia, on Saturday, December 6th, Dr. Zacur P. Boyer, aged sixty-seven years. Broell.—In Chicago, on Sunday, November 30th, Dr. Adolph J. Broell, aged forty-three years. Clark.—In Amherst, N. H., on Monday, December 1st, Dr. John Howe Clark, medical director, United States Navy, retired, aged sixty-six years. Crofford.—In Los Angeles, Cal., on Monday, November 24th, Dr. Thomas J. Crofford, of Los Angeles, Calif. Dean.—In New York, on Wednesday, November 26th, Dr. Adolph W. Dally, aged thirty-two years. Deely.—In Niagara Falls, N. Y., on Tuesday, December 2d, Dr. John M. Deely, aged eighty years. Dwelly.—In Fall River, Mass., on Thursday, December 4th, Dr. James Dwelly; aged sixty-six years. Elmo.—In Elmo, Ala., on Wednesday, November 26th, Dr. William M. Edwards, aged ninety-one years. Finney.—In Orono, Va., on Sunday, November 23d, Dr. Edward B. Finney, aged seventy-eight years. Frazer.—In Canton, Ohio, on Wednesday, November 26th, Dr. John Decker Frazer. Goodyear.—In Groton, N. Y., on Tuesday, November 25th, Dr. Miles D. Goodyear, aged sixty-seven years. Green.—In St. Louis, Mo., on Sunday, December 27th, Dr. John Green, aged seventy-eight years. Greenleaf.—In Lawrence, N. Y., on Wednesday, December 3d, Dr. Richard Cranch Greenleaf, of Lenox, Mass., aged sixty-seven years. Harper.—In Washington, D. C., on Thursday, November 27th, Dr. George Henderson, aged seventy-one years. Howard.—In Dallas, Texas, on Friday, November 28th, Henry P. Howard, aged eighty-four years. Hunter.—In Columbus, Ohio, on Sunday, November 30th, Dr. Ham Hunter, aged fifty-two years. Kemper.—In Galesburg, Ill., on Friday, November 28th, Dr. John Kemper, aged eighty years. Lanza.—In Pittsburg, Pa., on Sunday, December 1st, Dr. Frank L. Lanza, aged seventy-four years. Merrill.—In Peperill, Mass., on Tuesday, December 2d, Dr. William Hutchinson Merrill, aged fifty-three years. Miller.—In Baltimore, Md., on Sunday, November 23rd, Dr. William E. Miller, aged forty-two years. Montell.—In Baltimore, Md., on Sunday, November 23d, Dr. Henry K. Montell, aged thirty-one years. Morse.—In Gloucester, Mass., on Tuesday, December 2d, Dr. George Morse, aged eighty years. Newcomb.—In Champaign, Ill., on Tuesday, November 25th, Dr. William Kendall Newcomb. Notte.—In Reed City, Mich., on Wednesday, November 12th, Dr. Harry S. Notte. Nott.—In Brownsville, Texas, on Monday, November 24th, Dr. Thomas E. Nott, of Spartanburg, S. C. Parker.—In Waco, Texas, on Wednesday, November 25th, Dr. J. T. Parker, aged seventy-six years. Rich.—In New York, on Thursday, December 4th, Dr. Albert Rich, aged sixty-eight years. Usilton.—In Philadelphia, on Wednesday, December 3d, Dr. Charles A. Usilton, aged fifty-nine years. Van Ness.—In Chatham Centre, N. Y., on Tuesday, December 2d, Dr. Sherman Van Ness, aged fifty-four years. Walker.—In New York, on Thursday, November 27th, Dr. Robert Alvin Walker, aged fifty-nine years. Yerkes.—In Alton, Ill., on Thursday, November 27th, Dr. Titus P. Yerkes, aged seventy years.
Original Communications.

THE QUESTION OF DIABETES AT THE INTERNATIONAL CONGRESS OF MEDICINE IN LONDON.

By R. Lépine, M. D.,
Lyons, France.
Professor Emeritus of Medicine, Faculty of Medicine,
University of Lyons.

There has hardly been a medical congress for the past twenty years at which the question of diabetes mellitus has not been discussed; in view of the frequency of the disorder and the ever increasing literature on the subject this is not to be wondered at. At the International Congress of Medicine held in London during the past summer two most interesting papers were presented. Unfortunately, they have not yet appeared in full.

Unstinted praise is due Dr. George Dock for the admirable manner in which, in treating of the pathogenesis of the subject, he emphasized the existence of several factors in the etiology of the disease. It is through combinations of these different factors that the special characteristics of individual cases are produced—just as from various combinations of the letters of the alphabet there can be formed an infinity of words. Formerly there were thought to exist a nervous diabetes, a pancreatic diabetes, an arthritic diabetes, etc. Theoretically, such a classification may seem easily justifiable; clinical examination of a diabetic, however, will nearly always demonstrate an association of several factors in the causation of the disease. Thus, if a subject becomes diabetic after a fall on the head, this is not due alone to the injury, but to a predisposition, as is proved by the fact that not in every one receiving an injury to the head does diabetes develop. Extensive sclerosis is often found post mortem in spite of the absence of diabetes during life.

Doctor Dock proposes seven pathogenic factors for the disease, but this number is open to discussion. Personally, I am not convinced that there are seven cognate etiological factors. The factors of secondary importance appear to me, however, to be numerous, for science is daily adding to the number. Among the important factors several can be broken up further, e.g., the nervous factor, which is certainly operative in several ways.

Lesions of the pituitary body and of the superior cervical ganglion (of the effects of which Doctor Dock gave a detailed analysis based on the experiments of Weed, Cushing, and Jacobson) act in a different manner from puncture of the floor of the fourth ventricle; for the stimulus which such a puncture produces is transmitted to various organs, the capsules, the liver, and even to the entire economy by way of the spinal cord, down to the first dorsal segments (Wertheimer), whereas according to the investigators already named, electric stimulation of the pituitary body is followed by glycosuria even after section of all nervous pathways. If this is actually the case, one would have to deal, not with a nervous action, but with the action of the internal secretion of the hypophysis, this furnishing, moreover, a new illustration of the importance of the internal secretions provided the basal chain of neurons which, according to Sajous, connect the pituitary with the thyroid and adrenals, were also severed. Additional proof is supplied by the frequent incidence of diabetes where atrophy of the pancreas decreases its internal secretion.

Doctor Dock justly accords an important place in the pathogenesis of diabetes to the diminution of general glycolysis. It is somewhat surprising, however, that he fails specifically to mention the constitutional condition (cellular, no doubt), usually arthritic, which in certain subjects with a hereditary predisposition diminishes glycolytic power in the organism at large. If after the ingestion of 200 grammes of sugar an arthritic patient excretes a larger amount of sugar than a normal subject (and that is the case can readily be shown), it is because his cells do not function normally. Ebstein, as is well known, epitomizes this cellular abnormality as follows: In gout the protoplasm of the cell is normal, while the nucleus is diseased, as is shown by the increase of the endogenous purin bodies; in diabetes and in obesity, on the other hand, the nucleus is healthy and the protoplasm diseased, though in a different manner in the two conditions; the obese individual fails perfectly to oxidize his fats, while the diabetic patient does not properly break down his glucose.

Be this as it may, we must, I repeat, congratulate Doctor Dock for having well recognized the value of diminished glycolysis, all the more since his collaborator in the report presented, Doctor von Noorden, denies—with justification indeed—this diminution of glycolysis any rôle in the pathogenesis of diabetes. In this connection it is to be noted that Doctor von Noorden stands almost alone in the position he takes, his view not having even been recognized by his most devoted adherents. His error is rendered manifest by the fact that in cases of grave diabetes, as Haenriot was the first to observe, ingestion of one hundred grammes of glucose does not cause an increase in the respiratory quotient, as it would in a healthy subject. This signifi-
cant finding is corroborated by the results obtained as regards glycosylation either in an isolated and perfused organ or in vitro. Among the experiments on the isolated heart, those of Starling and Knowlton appear to me conclusive, in spite of the criticisms directed against them, and as for my own experiments in vitro, carried on through a period exceeding fifteen years, they can leave no room for doubt in the matter. 1 To the results of glycosylation in an isolated organ or in vitro an attempt has been made to oppose the facts brought out by Levene and Meyer (Journal of Biological Chemistry, xi, 1912, p. 347), showing that the apparent decrease of glucose may be due to a condensation and not to destruction of the sugar. In this connection I shall merely call attention to the fact that this interesting phenomenon of condensation never occurs in experiments of brief duration. Our own never lasted over an hour, and, with due reservation of statements made in the Journal de physiologie, 1911, p. 184, the destruction of sugar may be taken as a certainty.

If I insist upon the decrease of glycosylation in diabetes it is because I am convinced of its practical importance. I am certainly aware that in certain forms of diabetes there is an exaggerated formation of sugar at the expense of the aminoacids. But this is not a matter of primary importance. This view of the decrease of glycosylation in diabetes affords an important therapeutic indication—that of increasing glycolytic activity. Now, diet is not the sole means of accomplishing this. At the London congress dietetic regulation was declared to be the only treatment for diabetes. This is an exaggeration, and I maintain that the treatment of diabetes does not consist entirely in prescribing oatmeal and fats. As I have stated elsewhere (see Le Diabète sucré) the diabetic patient must be treated medicinally. He must be thoroughly examined, every abnormality of nutrition sought out, and an attempt made to restore the nutritive state to normal. Diet, to be sure, is essential in the treatment of diabetes; but generally there is something to be ordered besides. To throw aside all medicinal measures is a mistake: not that there exists at this time any specific for the disease, but because this or that drug may correspond to some indication in a given individual. For example, I have seen a patient who could not do without quinine, though he was not malarial. Another may do well on opium, etc. I do not refer in this connection to the alkalies, the utility of which is generally recognized; nor should physical agencies be entirely overlooked. It is well known that glycosuria is increased by a low surrounding temperature, and that a moderate degree of heat decreases it. Why, then, is climatotherapy so little availed of? Massage is almost always very useful.

The final word on the treatment of diabetes was by no means spoken at the London congress. This need occasion no surprise: international congresses are rather solemn affairs, which lack the calmness and concentration necessary to bring out clearly all the essential features of a question.

1 There is a résumé of these experiments, see Lépine, Le Diabète sucré, Paris, 1909, p. 121, et seq. ORBIAL ABSCESS FROM INFECTION THROUGH THE ETHMOID. 2

By John O. Roe, M. D.,
Rochester, N. Y.

The intimate and important relations existing between the ethmoid labyrinth and the orbital cavity are well illustrated in the following cases of orbital abscess resulting from an acute extension of an ethmoid infection, which I herewith report. This intimate relation is also shown in the frequent disturbances of vision that result from nerve irritation, reflected from the nose to the retina and to the ocular muscles—that irritation being caused by intransal pressure, the result of various diseased conditions of the turbinate bodies and of the accessory sinuses.

Onodi, who has given this subject more attention than any other observer, has in his book, The Optic Nerve and the Accessory Sinuses of the Nose, clearly shown how this takes place through the anatomical connection of the two regions. Notwithstanding the fact that many cases of visual defects and disturbances from nasal and accessory sinus diseases are reported by different observers, the subject is not given the attention it should receive. Many chronic visual defects and also many chronic headaches that are attributed to these visual defects go unrelieved, because the fundamental cause of the disturbance in a large proportion of cases remains unrecognized.

The two cases of ethmoid disease in the acute form, illustrating this intimate association of the ethmoid sinuses with the orbital cavity, which I herewith report, are of special interest, the first one particularly so because it illustrates not only the readiness with which ethmoid diseases may extend to the orbit, but also the ease with which the orbital cavity can be reached and abscesses of this region opened by the nasal route.

CASE I. Stanley Gilmore, aged seventeen years, was brought to my office on the morning of August 10, 1911, by Doctor Carpenter, Rochester, N. Y. The young man was suffering from an extremely swollen condition of the tissues of the right orbit and of the surrounding parts, completely closing the eye. The history of the case is as follows: On July 26th Doctor Carpenter was called to see the boy and found him suffering from a sore throat and cold in the head. He continued to grow worse and soon began to have some swelling about the right eye. From July 20th to August 6th he remained in much the same condition, except that the swelling about the right eye increased so much as to amount to a general cellulitis. The swelling covered nearly the whole side of the face, but was more prominent about the eyeball, causing a well-marked bulging and discoloration. The upper eyelid and the parts immediately above the eye were swollen, so much so that the patient was able to see with this eye only when the eyelid was raised. When the eye was opened he could see dimly, although he said the sight seemed very much blurred. The case being urgent, the temperature was increased to 103° F. I decided to operate at once. As the pain and swelling were most intense directly back and above the eye, it seemed to be a complication of an acute frontal sinusitis, producing what appeared to be a subperiosteal abscess, involving the orbit and the supraorbital region. But on examining the nose, the turbinates and other parts were found markedly swollen, with a mucopurulent discharge coming from the ethmoid region. It was quite evident, therefore, that the orbital infection had come from the nasal infection, which was manifestly re-
lated to the sore throat that he had had for several days previous to the ocular involvement.

In order, however, to settle the question regarding the presence of a subperiosteal abscess above the orbit, I made a deep incision with a slender knife down to the bone, just to the right of the supraorbital notch. As no pus was found in this region, it was clearly evident that we had to deal with a complication of the rhinitis and ethmoiditis only. Moreover there were found, after a careful examination, no further indications that the other accessory sinuses were involved.

As the ethmoid cells were unquestionably the source of the orbital infection and abscess, the logical method for opening this abscess was through these infected cells by the nasal route. Cocaine was applied to the interior of the nose, and by the use of a small amount of chloroform the pain of the operation was avoided. After removing the anterior portion of the large middle turbinate, I went through the posterior ethmoid cells and the posterior portion of the orbital plate, using an angular pair of cutting forceps, which I had specially designed for these operations. Very little resistance was encountered, as the osseous structures had evidently become necrotic and very much softened. As soon as the abscess cavity was reached, pus began to flow into the nose. I immediately enlarged the opening sufficiently to give free vent to the pus, and by pressing gently over the eye the pus flowed out in a stream, until we estimated that fully an ounce had escaped. After getting out all the pus obtainable, I irrigated the nasal cavity with a warm saline bichloride and boric acid solution, one to 5,000, and the nasal cavity was packed loosely with iodoform gauze. A mild pressure with a bandage was made and maintained over the orbital region to force out gently whatever pus remained or might continue to accumulate from the disintegrated tissues. The cellulitis, together with the orbital infiltration and swelling rapidly subsided, so that at the end of ten days they were almost gone, and the boy made a complete and uneventful recovery.

The accompanying illustration shows the swelling about the eye when it had about one half subsided.

Case II. Another exceedingly interesting case came under my observation about three months later. On October 20th, I was called on the telephone by Dr. L. P. Conley, to come to Clifton Springs to see a young man, nineteen years old, who had an enormous swelling of both eyes and was becoming more or less delirious. When I reached there I found the young man in a semiconfused condition with evidently a septic cellulitis of the orbital region on both sides. The history of the case showed that the young man about ten days before had injured his hand with a rusty nail, the wound becoming immediately infected. Directly afterward he began to have a cold in the head, evidently the result of inoculating himself by picking his nose with the infected hand, thus causing an acute infection of the ethmoid cells.

He grew rapidly worse so that the morning I saw him he was becoming delirious and somewhat comatose. The marked bulging of the eye, the cellulitis, and discoloration of the orbital tissues very much resembled the condition in the case previously described. The temperature at this time was 105 F., and we were undecided as to whether the brain disturbance was due to pressure from orbital infection and probable abscesses or to a meningitis. If due to a meningitis there was absolutely no hope for his recovery, but if due to the pressure from the orbital infection there was some hope for him. Therefore, in order to give him the benefit of this doubt and every possible chance, I at once proceeded to open into both orbits, through the posterior ethmoid cells in about the same manner as described in the previous case. More or less bloody pus came away, but not in any considerable quantity as in the previous case. The young man, however, did not rally as we hoped after the removal of this apparent orbital pressure, but continued to grow rapidly worse and died the latter part of the afternoon of the same day. An examination was made shortly after by Doctor Webb, pathologist of Clifton Springs Sanitarium, who found this orbital phlegmon and infectious ethmoiditis to be associated with an acute meningitis and a general streptococcus infection, which we believed to be the case when no relief was obtained from the operation.

While such cases are rarely met with, they are sufficiently frequent to emphasize the importance of giving careful attention to the ethmoid labyrinth in all cases of orbital abscess. In the first case the infection was entirely local, while in the second case the streptococcus infection was general, although the meningial involvement was probably secondary to the same infection that caused the orbital phlegmon, having extended to the meninges through the cribiform plate.

While the ethmoid sinuses are those most closely connected with the orbit, orbital abscesses are sometimes associated with disease of the other sinuses, and even with all of them at the same time, being the result of the same infection.

Villeneuve (Clinique chirurgicale, 1801) reports a case in which not only the ethmoidal, frontal, and maxillary sinuses were involved in association with the orbital abscess, but the phlegmon extended to the meninges. The frontal sinus was opened and the opening continued through into the cranial cavity. The cranial abscess was drained through this opening and the patient recovered. Grunenw (Mount Sinai Hospital Reports, N. Y., iii, 487, 1903) reported a similar case in which the patient died. Wilson (Laryngoscope, xvi, 1906) reports a case of empyema of the frontal, ethmoidal, and sphenoidal cells, associated with abscess of the orbit and followed by severe meningitis, optic neuritis, and otitis media. The abscess was opened by a Kilian operation and the patient recovered. In this case drainage was maintained through the wound although Wilson states that pus was exuding into the nostril through a hole about the size of a dime in the orbital plate.

Harlan (Philadelphia Medical Journal, viii, 93, 1901) reports a case of abscess of the orbit with disease of the ethmoid. In this case Jansen's operation for empyema of the frontal and ethmoidal sinus was employed, except that, instead of packing the cavity with gauze, as Jansen does, drainage through the nostril was used and the wound sutured.

Oliver and Wood (American Journal of the Medical Sciences, cxxiv, 42, 1902) report a case of
orbital abscess associated with antral and sphenoidal disease. The case was that of a girl, thirteen years old, and the obscurity of the different conditions giving rise to the trouble made the diagnosis difficult and of long delay. In this case the abscess was opened by an external incision through the lower eyelid and the antral abscess through the canine fossa, drainage being instituted through the external wound.

Roy (British Medical Journal, 11, 1864, 1906) reports a case of orbital abscess simulating a malignant growth, but on attempting to remove the supposedly sarcomatous eye, an orbital abscess was revealed by a gush of pus through the preliminary opening made for the removal of the eye.

In nearly all the cases reported the orbital abscess has been opened by an external incision, either a Killiani or a Jansen operation. This method is necessary in all such acute cases when the frontal sinus requires opening; but when the orbital abscess is associated with inflammation of the ethmoid, maxillary, or sphenoidal sinus only, the logical way of opening the abscess is by the nasal route. In the case of orbital abscess reported by Posey (Pennsylvania Medical Journal, vi, 414, 1902-3) he referred the case for an examination to Doctor Packard, the consulting rhinologist of the hospital, who readily evacuated the orbital abscess through the posterior ethmoid cells. Cases of orbital abscesses, however, that come under the observation of the oculist and the general surgeon, are almost invariably opened by the external route.

In considering the comparative advantages, disadvantages, and dangers of the operation for the opening of orbital abscess by the external and internal route, certain points in the technic must be considered. By the external route, the operator has the advantage of direct ocular inspection of the work as he goes along, is enabled to follow the course of the diseased process in whichever direction it may lead him, and can also directly control any hemorrhage that he may encounter. On the other hand, the disadvantage of the external route is the external disfigurement, which, more or less, follows such operations, sometimes amounting to a considerable deformity.

The advantages of the internal route are many and important. In the first place, the opening is made into that portion of the orbit where the abscess and phlegmon are generally most concentrated. This is particularly true in all those cases in which the orbital abscess has resulted from infection through the ethmoid. We are also following the disease from its source and at the same time removing or eliminating the source of the infection in the ethmoid cells. There is also entire freedom from the danger of disfigurement or deformity; and we are giving drainage to the abscess through the most direct route. The relief is speedy and the complications of the external wound are avoided.

In those cases where the frontal sinus is involved, even if this is not discovered until after the opening through the ethmoid has been made, it does not preclude a direct opening into the frontal sinus externally if found necessary, but, on the contrary, affords a more direct and effectual drainage.

The comparative danger attending the two operations depends entirely upon the technic of the operator. In either case a bungling operator may do irreparable damage, when in proximity to the cranial cavity; but with a skillful technic and a thorough knowledge of the anatomy of the parts, the internal operation can be made as safe as the external.

I will not attempt to mention any points of the external operation so commonly done and quite familiar to you all, but I will mention some of the points that I have found most important to observe in an operation for entering through the posterior ethmoid cells. On beginning the operation, the first and most important thing is to locate the posterior wall of the nasal cavity, throughout its entire extent from the cribiform plate to the basilar process. Unless this is carefully and accurately done, so that the exact depth of the nasal chamber at every point is known, no operator should attempt to open the posterior ethmoid cells, because he would be uncertain as to whether he was penetrating an ethmoid cell or the cranial cavity.

In examining a skull, the cranial cavity is always found rounded at this region so that the cranial contents lie posterior to a line drawn at right angles to the posterior nasal wall. Therefore, by locating the posterior nasal wall accurately, and going in laterally at right angles to the anterior plane of the wall, the posterior ethmoid cells can be opened with the utmost ease and accuracy, and with entire freedom from the danger of penetrating the cranial wall; whereas by penetrating these cells anteroposteriorly, we have no certainty as to when we have reached the last posterior wall, or the anterior cranial wall.

The instrument which I mainly use in penetrating these cells is a forceps cutting at right angles made right and left for the respective sides. I use for locating the posterior nasal wall a slender, thin, flat steel probe, which will much more readily pass obstructions than the slender round silver probe, so commonly used. This little instrument, which is most serviceable in all nasal work, I have designated as my long finger with an eye at the end of it, as it indicates to me the exact situation and condition of the different parts of the nasal chamber, and is a very material aid to direct or indirect inspection.

It may be supposed that there is danger of increased infection following through this opening into the orbital cavity; but this is more imaginary than real, for we are removing rather than spreading the infection already present. In other cases in which I have been very desirous of removing all infected ethmoid cells and where the os planum happens to be unusually thin, I have opened into the orbit, and in no instance have I ever had any ill effects.

Therefore, it is readily seen that with a thorough knowledge of the anatomy and the particular configuration of the nasal chamber and its posterior wall, readily ascertained by the method which I have described, the opening of the orbital abscess by the internal route is easily, accurately, and safely made. It is also free from all dangers of disfigurement, while it is the most direct, the most logical, and the most desirable method for opening orbital abscesses in cases where the infection has entered through or extended from the ethmoid cells.
EPILEPSY.

By E. H. Mullan, M. D.,
New York,
Passed Assistant Surgeon, United States Public Health Service.

Epilepsy is derived from the Greek ἐπιλέψις, which means a laying hold of. It is the strangest disease known to man and has existed in all ages. Man and woman, young and old, rich and poor, are the victims of this physical mental disease. In ancient times the epileptic was considered a sacred person, hence the name morbus sacer (sacred disease). Later on just the opposite view was taken of the disease; the epileptic was then considered as one possessed by devils. We now know that epilepsy is a brain disease. It will be convenient, in describing epilepsy, to consider it under two separate headings: namely, (a) the epileptic attacks and (b) the epileptic.

THE ATTACKS.

The principal variety of attack in epilepsy is the familiar convulsion in which all body parts participate; it is known as the grand mal type or major epilepsy.

In almost half of the cases the general convulsion is preceded by a certain premonitory symptom known as the aura (apnea—a breath), which for the same patient is usually the same in every attack. In many patients the following auras have been noted: Peculiar sensation in the head, a kind of vertigo; flashes of light before the eyes, or the apparent seeing of an animal or other object; ringing or roaring sounds in the ear; an uncomfortable sensation in the abdomen, a grinding or burning abdominal sensation which usually extends in an upward direction; sharp pain in the same region; the noticing of a peculiar odor or metallic taste; pins and needles sensation in the arms, legs or elsewhere; an object slowly becoming larger or smaller to the view; a definite thought or word may occur to the patient's mind; a brief period of joy and ecstasy may occur; rapid mental activity may occur in which thought after thought occurs in quick succession; sudden twitching of a muscle or muscle group; dancing; running in a circle; whistling; moaning; etc.

After the persistence of the aura or premonition, anywhere from a second to thirty seconds or more, the patient suddenly loses consciousness, as if struck by lightning, and falls to the ground. Serious injuries, such as fractures, dislocations, bruises, burns, may result from these terrific falls in which violent muscular contraction often plays a part. This lightning fall, if not accompanied, is immediately followed by a strong and general muscular contraction (the tonic spasm). The trunk muscles are strongly contracted, the violent muscular action rigidly extends the legs and arms, or these extremities may assume a position of flexion. The air is forcibly driven from the lungs and produces a sharp cry in many cases. The face turns pale, to be followed later by a purplish or bluish discoloration (cyanosis). The eyes are staring and fixed, and appear as though they would pop out of their sockets. The head is usually turned to one side. After this continuous contraction of the muscles has lasted for a half minute or less, the stage of clonic spasm begins, which lasts usually from one half to five minutes. This appears to be an intermittent jerking of all the body muscles. The saliva is churned up and exudes from the mouth as a frothy fluid. The tongue is frequently bitten. The thumb covered by the fingers is buried in the palm of the hand. The head, arms, fore-arms, wrists, thighs, legs, and feet twitch, jerk, and contract until what has seemed to be a really long time, has actually been only a minute or a little more. The urine may be voided during this stage. A period of relaxation then supervenes; the patient is now in a deep stupor, and the exhausted muscles are at rest. Half an hour later the patient may come out of the stupor with a clear mind or in a dazed condition or in a state of actual delirium. Frequently the stupor turns into natural sleep. These attacks are sometimes induced by sleep and are then spoken of as nocturnal epilepsy. This form of epilepsy has occurred in certain people a year or more before it has been discovered. In one who wakes with sore and aching muscles as if he had been beaten, and if his tongue is sore or bleeding, from having bitten it, if he has unconsciously voided his urine or feces in the bed during the night, epilepsy is to be suspected. If, in addition to these symptoms, a paralyzed or greatly weakened group of muscles is found, and these muscles rapidly regain their strength after awakening, a nocturnal epileptic attack can be diagnosed with certainty.

A small proportion of epileptics have what is known as the minor epileptic attacks or the petit mal type. In these spells there is a momentary loss of consciousness. During a conversation an afflicted person will suddenly turn pale and become dazed (momentary unconsciousness). There may be slight twitching of facial muscles, especially those about the mouth. The patient often describes the attack by saying that "I knew nothing for a second." Then he regains consciousness, continues the conversation, or continues to perform any act which he had begun, apparently as if nothing had interrupted him. These petit mal attacks may, as in the grand mal type, take place either during the day or night, and they may, as in the first type described, be preceded by an aura or delirious behavior, or they may be followed by delirious behavior. Some patients are the victims of both kinds of epilepsy, the grand mal seizure occurring at one time and the petit mal occurring at another. In some instances the patient emerges from the physical epileptic attack only to enter upon a mental attack. The mental attack varies in nature and duration, not only in different subjects, but also in the same patient at different times. He may be simply confused, mixed up, dazed, stupid, or act in an automatic manner, which state may subside in a short time, or he may be in a state of wild delirium, raging, running amuck, doing damage, inflicting injury to others as well as to himself, which may persist for hours or even days. It is during this stage of delirious behavior that all sorts of ill deeds are committed. A patient at such a time may indecently expose himself, commit an immoral act, or he may be the perpetrator of thefts, cruel acts, arson, homicide, and, in fact, every crime known
MULLAN: EPILEPSY.

1198

to man. At this time there is usually extreme clouding of consciousness, the patient says many curious things, and performs strange acts, sometimes in an automatic manner.

When the delirium subsides and consciousness is completely regained, the patient may possess a fragmentary recollection of what has recently happened. As a rule, however, he has no memory for the events which have occurred during the time of delirious behavior. In some epileptic attacks the physical convulsion is mild in degree and short in duration; it may escape observation and the mental phase come prominently forth as the real attack. In many criminal cases these attacks become important from a medicolegal point of view. In the repeated juvenile offenders (800 consecutive cases) who have been brought before the Chicago courts, Doctor Healy has found that seven and one per cent. of them are epileptics.

Some patients immediately preceding a grand mal or petit mal attack will have a fit of ill humor in which they will be conscious, dazed, or delirious. Before the physical seizure, they may be depressed, uneasy, restless, excited, and angry or in a really high strung condition, and the convulsion will clear the atmosphere and bring about a state of relief and mental repose. The dipsomaniac or periodic drinker is closely allied in his nature and behavior to the epileptic. Have we not all seen a man of fine parts, apparently in good health, doing good work and performing real service, become depressed, uneasy, nervous, and irritable? Then suddenly with an irresistible force he plunges into alternating bouts of hard drink and deep sleep, only to come to at the end of a week or so in a changed, relaxed, subdued condition, with only partial memory for what has occurred during the preceding week. During these states of delirious behavior or befogged condition, the patients are disoriented, that is, they do not know where they are, nor to whom they are talking; they are confused and do not comprehend questions and wander about in an aimless way. These befogged states occurring before, and especially after, the physical attacks are spoken of as preepileptic and postepileptic insanity, and it is during these periods that some epileptics have to be removed from their homes to hospitals, jails, or other custodial places; in institutions at such times they receive special care and attention.

Some physical conditions and many peculiar mental states occur in epileptics at times when the convulsion is absent or apparently absent. These states are known as epileptic equivalents. They are supposed by many neurologists to replace the fit. An example of a physical equivalent is the occurrence of a sudden attack of profuse sweating in one who is also subject to occasional convulsions. The mental equivalent, the one that generally occurs, is also called psychic epilepsy. Some authorities contend that a physical convulsion perhaps so small as to escape observation, occurs in every one of these mental states. It is during this psychic attack or delirious behavior that all sorts of strange antics and peculiar emotional disturbances are gone through, and of which the epileptic usually retains no recollection. They occur in those patients who have physical seizures at long intervals. During these psychic attacks the patient wanders about in a dazed manner; there is more or less clouding of consciousness. He moves automatically, as if some outside force controlled his movements. His actions are purposeless. He answers questions in an unintelligent way, and grumbles and fusses with those about him or with imaginary people. The epileptic in this condition is temporarily deluded and in some cases hallucinations are prominent, that is, he sees imaginary things and hears imaginary voices and sounds. During this period patients may indulge in all sorts of doings: such as masturbation, exposing themselves, bestial and perverted sexual acts, attempts at rape, setting fire to houses, desertions, pillerings, and dreadful assaults. At such times they have been known to cut to pieces their own parents, to stab, to shoot, and to perform all sorts of brutal outrages. Most of these acts are without a purpose and there is no attempt on the part of the patient to conceal them. Sometimes victims run away to escape from their imaginary persecutors. They may shout and shriek and run about doing much damage to property and persons. Sometimes they go about in a dreamlike manner with happy countenances showing that they are all full of ecstatic joy. In this joyful mood they imagine that they are waltzed to heaven or that they see the golden gates on the earthly shore. There is only partial recollection of these events or there may be no recollection at all for the entire psychic attack. You can readily see why in all these attacks it is so essential to look carefully for a convulsion, a minor epileptic attack or other evidences of epilepsy. It is well in these cases to search carefully the patient's history of long years ago. "Status epilepticus" is where the seizures are continued one after another with very short space of time between them. Unconsciousness is continuous and between fifty and two hundred convulsions occur in twenty-four hours. A fourth of the patients die in this state.

THE EPILEPTIC.

To-day there are some epileptics who are doing good work and are accomplishing things in the world of events; as far as can be observed they are not suffering with mental impairment. These particular cases are exceptional. In almost all epileptics there is some mental impairment and this is present in every degree from slight defect of memory all the way to conditions of profound dementia (impairment and destruction of mental faculties). The more frequent the seizures the more prominent the dementia. In fifty per cent. of the patients the dementia is mild and can be detected only by a trained observer. The character and disposition of epileptics possess certain things in common, they also possess traits that are entirely different in different individuals; breed and blood count here just as in normal persons. Many of them are over religious and spend much time in praying and bible reading. They follow the familiar lines of thought, which as the dementia increases becomes more and more restricted. Into their conversation they inject hackneyed expressions, stilted phrases and pious sayings. As the mental horizon diminishes the egoism increases and in ordinary conversation they may
praise themselves and their belongings. They are apt to be pleased with themselves and may be ceremoniously polite. While they forget many events of their present and past life, they may be able to express themselves clearly in their narrow thought field. At times epileptics are peevish, obstinate, stubborn and unruly. Sudden changes in mood from depression to elation and the reverse are apt to occur. They are irritable, easily angered, and fly into a rage without due provocation. It is then that they become threatening and dangerous and show a complete lack of self control.

In this wild anger they may curse, strike and injure those who unluckily happen to be near. Attacks of ill humor are especially apt to occur in the early morning. An epileptic may get out of bed in an irritable and vicious mood; he will then answer questions in monosyllables, his fault finding and cursing may quickly change into furious rage. With wild terror in his eye, he may break dishes, hurl objects to the floor, smash windows, strike with terrific blows those about him and finally come to rest in a relaxed, amiable and subdued condition, feeling a sense of relief for having given vent to his feelings. In some, these attacks of ill humor are periodical and may precede or replace an actual convulsion, in which case they would be known as equivalents.

Grassett 1 thus sums up the epileptic character: "On the one hand they are sombre, taciturn, defi ant, suspicious, always ready to fly into a passion, to hurt people, to become enraged and to strike; on the other hand they are obsequious, obliging, wheel-like, full of effusion and gentleness."

In reality epileptics are all or nearly all irritable, subject to attacks of sudden, violent, and ferocious transports of rage, during which time they do not, as it were, belong to themselves. This irritability is the keynote of their character. Many have in addition vices and perverse instincts; many are greedy, violent. . . . They frequently have a tendency to a sickly piety or a sort of excessive religiousness, mixed hypocrisy." 2

PREVALENCE AND CAUSE.

It has been estimated by observers who have made intensive studies of various localities here and abroad that the number of epileptics in well to do countries is one to every five hundred of the population. In poor countries the ratio is somewhat greater. In the United States with its population of ninety million people there would therefore be one hundred and eighty thousand epileptics.

Heredity plays a most important part in the production of epilepsy. In almost all cases there is a strong hereditary tendency toward the disease, which exists from birth. In sixteen per cent. of the cases, epilepsy exists in one of the parents or grandparents. In fifty per cent. of the cases insanity, feeble mindedness, hysteria and other neuroses existed in the parents. Fifteen per cent. of these people have alcoholic parents. Brain injury at the time of birth and subsequent to birth is a potent cause. Other causes are syphilis, tuberculosis, infectious diseases (scarlet fever), and emotional causes such as fright and shock. Where the inherited soil is favorable for the development of epilepsy the exciting cause may indeed be very slight.

EPILEPSY AND THE STATE.

Five to ten per cent. of these unfortunate are curable if proper treatment is instituted. This percentage includes all cases, even cases of considerable duration. Cases that are taken in hand early in life and placed in suitable hospitals or colonies offer the best chance of recovery. The greater number of epileptics seek institutional care when the disease has made its ineradicable stamp upon them. During the year ending September, 1911, there were admitted 272 patients to Craig Colony, New York. One hundred and twenty-three (123) of them were twenty years of age or under and one hundred and forty-nine (149) were over twenty years. In 219 of these 272 cases the age at which the disease first occurred was under twenty-one years. These figures show that although the majority of cases begin early in life, they do not enter institutions until well advanced.

Epileptics are placed in hospitals when custodial care is necessary on account of the trouble and danger which they cause at home. The hospital or colony for epileptics is the place par excellence to place these unfortunate people, and that too, early in life, as soon as possible after the onset of symptoms. In many instances the poor epileptic, if a child, is early excluded from school. He is often shunned by the children of his neighborhood, who cannot understand him. At home, on account of his seizures and peculiar disposition, he is a constant source of trouble. When company comes he is hustled out of the way in order that they may not be made uncomfortable and that the family may not be mortified. There is constant anxiety for the family when the epileptic is away from home and, as a result, his visits to places of amusement and recreation become fewer and fewer. Debarred from school, and being poor or in moderate circumstances, it is impossible for him to obtain instruction in intellectual pursuits or manual training which would enable him partially or completely to be self supporting, and which would cheer his life and retard to some extent the demoting process. Owing to his disposition and likelihood of attacks

---

1 Taken from the pamphlet of the National Association for the Study of Epilepsy. Translated by Jelliffe; Funk & Wagnals.
he cannot occupy a position of responsibility, even if he has received a fair degree of education. As he advances in age and his disease becomes more extensive, his life is narrowed to the home where, owing to unavoidable circumstances, his physical and mental condition in many cases runs a rapid downhill course.

As I said before the place for such an unfortunate is in a hospital or colony especially designed and conducted for the care of epileptics. Briefly, the advantages of such an institution are these:

1. For economic reasons, a collection of patients in a colony or hospital can receive the most modern care and treatment, the like of which could not be furnished to an individual.

2. The patients in such a place lead a well regulated life under careful supervision. Exercise, amusement, food, baths, work, medication, etc., are carefully prescribed to suit individual cases.

3. The patients have the benefit of experienced physicians and nurses who are constantly becoming more expert.

4. "Idleness is the devil's workshop," is especially true in regard to epileptics. At these colonies various kinds of work can be afforded as best suited to the degree of learning and need of the individual. On colony farms, outdoor work, which is so beneficial, can be afforded. Farm work, gardening, dairy work, poultry raising, can be indulged in, and the progress of dementia is thus retarded.

5. The colony is able to maintain a graded school with trained and experienced teachers.

6. In a few instances patients who are doing fairly well may be granted furloughs. These frequently act as real stimulants to the epileptic, and their visits home, often in an improved condition, are appreciated by their relatives.

7. Being fellow sufferers, the epileptics have sympathies and interests in common. They are thus enabled to bear their sorrows more patiently, and life is made comparatively happy for them.

8. In colony life, their physical and mental condition actually improves. This is frequently shown by the thin and delicate becoming stout and resisting soon after their arrival. The seizures become less severe and the interval between them often lengthens. In fact, their lives are prolonged.

9. In independent colonies, the epileptic, on account of his physical or mental fit, will not afford an objectionable sight to the feebleminded or other invalids with whom he is now often housed.

10. In such institutions the sexes can be separated, which is such an important step in preventing the reproduction of epileptics and other defectives.

11. Being together in large numbers, they afford the opportunity for clinical, pathological, and therapeutic research. Such research is benefiting and will continue to benefit epileptics, and it will be instrumental in diminishing the incidence of this dreadful malady.

At present in thirty-four States (including the District of Columbia), epileptics are cared for in public and private hospitals, sanitariums, institutions for incurables, pauper asylums, and homes. These unfortunate people are in many instances in places that are ill adapted to their needs, or they are at home, where they can receive little or no attention. They are a troublesome burden to the family, and in many cases a source of actual danger to the family and community. The neighbors of a vicious epileptic can all tell you a tale of woe. Even the learned judge and experienced juror are beginning to wake up to the fact that in many instances the repeated lawbreakers are the helpless victims of morbus sacer.

State hospitals or colonies established solely for the purpose of treating and caring for epileptics are nine in number. They are as follows:

Indiana: Indiana Village for Epileptics, New Castle, Indiana; patients, 114.

Kansas: Kansas Hospital for Epileptics, Parsons, Kansas; patients, 484.

Massachusetts: The Monson State Hospital, Palmer, Massachusetts; patients, 990.

New Jersey: New Jersey State Village for Epileptics, Skillman, New Jersey; patients, 392.

New York: Craig Colony for Epileptics, Sonyea, New York; patients, 1,420.

Ohio: The Ohio Hospital for Epileptics, Gallipolis, Ohio; patients, 1,447.

Texas: Texas State Epileptic Colony, Abilene, Texas; patients, 375.

Virginia: State Epileptic Colony, Madison Heights, Lynchburg, Virginia; patients, 121.

Other State institutions in which epileptics are cared for are:

Michigan: Michigan Home for the Feebleminded and Epileptic, Lapeer, Michigan; epileptic patients, 400.

Minnesota: Minnesota School for Feebleminded and Colony for Epileptics, Faribault, Minnesota; epileptic patients, 205.

Missouri: Missouri Colony for Feebleminded and Epileptic, Marshall, Missouri; epileptic patients, 140.

North Carolina: State Hospital, Raleigh, North Carolina; epileptic patients, 148.

Some other institutions caring for epileptics which are private or semipublic in nature are:

The Pennsylvania Epileptic Hospital and Colony Farm, Oakbourne, Pa.; patients, 76.

The Passavant Memorial Homes for the Care of Epileptics, Rochester, Pa.; patients, 63.

Silver Cross Home, Port Deposit, Maryland; patients, 24.

The Hospital Cottages for Children, Baldwinsville, Massachusetts.

The Brunswick Home, Amityville, Long Island, N. Y.

The list of private institutions is far from complete, so many hospitals and homes care for a few epileptics.

The following States now have laws which wholly or in part prohibit the marriage of epileptics: Connecticut, Indiana, Kansas, Michigan, Minnesota, New Jersey, Ohio, Utah, and Washington.

The public conscience in regard to the prevention of epilepsy and care of epileptics is now being
aroused in many places, and eventually every State will have its colony or colonies for epileptics. The colony will be the centre of research and instruction. From it will be sent forth many pills and serums which will instruct the public in regard to the prevalence, causes, and prevention of epilepsy. The colony will have a register of epileptics and physicians, and homes will be compelled by law to report all cases of epilepsy that come within their notice. This system obtains to-day in New Jersey, and perhaps in other States.

Field workers will also be attached to the colonies, and it will be their duty to collect complete family histories of colony patients and to perform field duties as may be required. The carefully chosen authorities of these institutions will, in the future, as they have in the past, make recommendations to the chief executive and State legislators in regard to the necessity for the enactment of laws preventing the marriage of mental defectives and laws dealing with the segregation of mental defectives—all of which laws when rigidly enforced will greatly diminish the number of epileptics and other defectives.

REFERENCES:

THE BACTERIOLOGY OF PYORRHEA ALVEOLARIS.

BY CLAUDE P. BROWN, M. D.,
Philadelphia.

The investigation of the bacteria present in pyorrhea alveolaris was taken up at the suggestion of Dr. Joseph Head, who has described the symptoms, pathology, and treatment of this condition by local measures supplementing the use of bacterial vaccines.

The name "pyorrhea alveolaris" was proposed in 1877, although it would seem to have been used before that time. While this name may not be scientifically descriptive, its use during approximately half a century has given it associations which cannot be misunderstood.

In 1550 Ambroise Pare made unmistakable reference to this condition. A study of skulls has convinced investigators that it is a disease of ancient as well as of modern man. Leeuwenhoek drew attention, as early as 1682, to what he called "animalcules" in material removed from the teeth. This material, however, was suspended in rainwater which at that time he regarded as being perfectly pure. Miller's work was devoted chiefly to a study of the bacteria of the mouth. It is of importance here on account of the location of the lesion, since the bacteria of pyorrhea are almost of necessity from mouth infection. Galippe and Harlan isolated two organisms and believed these to be the specific cause of the disease. Hunter quotes Arkowy who found that Bacillus gangrenae pulpa was present in ninety-five per cent. of cases with diseased pulp and dental caries. Dr. J. M. Riggs described this condition and demonstrated his method of treatment in 1886. In the paper read at that time, he states that he had recognized and treated it for twenty-five years previously. Vincentini made a microscopic study of the mouth flora, and recognized many of the fungus forms which are found in the mouth. Goadby seriously took up a study of pyorrhea bacteriologically in 1904, and in 1906 published his findings in eighteen cases. In the Erasmus Wilson lecture delivered in 1907 he reported a total of seventy cases, including the eighteen previously recorded. In that report streptococcus was found nineteen times; Bacillus necrosis dentalis was found fourteen times; Micrococcus catarrhalis, twenty-three times; Bacillus septus, fifteen times; Staphylococcus aureus, twelve times; the saccaromyces, five times; pneumococcus was found five times; Micrococcus citreus granulosis, six times.

In two cases reported in 1908 Streptococcus brevis, Staphylococcus albus, and the saccaromyces were found. Later, an anaerobe, the Bacillus necrosis dentalis, which Goadby calls a diplobacillus, was isolated. In 1909 it is reported that slide examinations revealed in addition to the others, a lepto-thrix Bacillus fusiformis, and three varieties of spirochetes. He was unwilling to credit to the Gram positive cocci entire responsibility for the infection. He believed that because of the early appearance and frequent association of certain bacilli and Micrococcus catarrhalis that they probably had etiological importance.

Eyre and Payne, in 1900, studied culturally a series of thirty-three cases. said to have been the filthiest coming to the dispensary at Guy's Hospital. The bacteria isolated were considered to be factors in causing the infection only when the opsonic index to them was particularly high or particularly low. Treatment was instituted with various containing organisms thus selected. These writers began, however, with the assumption that the bacilli were of no importance and discarded them, confining their work to the micrococci alone. In discussing this paper Goadby took exception to such exclusion. He did not agree that the best method of attempting to find out the particular bacteria related to any given disease was to make a special selection of the micrococci, confining one's attention to the estima-
tion of the opsonic index only with regard to the micrococi present. He found in his earlier work, in which the opsonic index was estimated for a large number of organisms present, that if the estimation had been confined to any one division, say micrococci, a number of them might be found to be related to the disease itself, but that some bacilli as well when tested also gave a low index. He said: "If the opsonic index has any value at all, if it showed a diminution or a large increase to any one organism, well and good; but if a large number of organisms were related thereto the chances were either that the opsonic index did not give all the knowledge required or the other organisms were also concerned in the infectious process." He had shown that some of the bacilli were concerned, at all events in the early stages.

Carmalt-Jones and Humphries reported five cases. *Streptococcus brevis* was isolated three times, in one case the findings were not reported, and in the others merely a statement was made that several organisms were isolated. The first four patients were treated with a vaccine containing *Streptococcus brevis*, the fifth with a vaccine containing *Streptococcus brevis* and staphylococcus.

In 1908 Mayou reported a case of staphylococcus infection of the eye following the removal of an infected tooth. This case is interesting from the fact that the infection did not clear up after the removal of the tooth, but extended to the orbit. Cure finally resulted only when staphylococcus vaccine was used. Bebbe notes fifteen cases of pyorrhea, in six of which the pneumococcus was present in practically pure culture. He says about the others merely that the growth was principally pneumococci with a small mixture of staphylococci. Vaccine treatment was instituted in all. Whittle asserts that he has isolated an organism which would grow in a twenty per cent. solution of formaldehyde. Best isolated a number of organisms, among which *Streptococcus pyogenes* and *Micrococcus catarrhalis* were the most common. Sims isolated a spirillum once, *Bacillus bacillis marinum* once, and another bacillus which he found difficult to grow.

Williams has reported a series of eight cases of pyorrhea treated with autogenous vaccines, also thirteen dispensary patients receiving stock vaccines. The vaccines contained only streptococcus or streptococcus and staphylococcus. For the cultural work the only medium used was plain agar. Logan made cultures from the teeth in ten cases of pyorrhea in human beings and three cases in dogs. This bacteriological work is of no value. Incipient, moderately advanced, and far advanced cases have been studied by Medalia. In a larger percentage of the 115 cases reported, opsonic index determinations and urine and feces examinations were made in conjunction with the bacteriological studies of the local lesion. The culture media used were blood serum, glucose bouillon, and blood agar. The last, however, was used only to establish the hemolytic properties of the streptococcus. Obviously bacteria that require hemoglobin for development were thus missed. His findings were as follows: Pneumococcus in chains in twenty-six cases; pneumococcus in chains and staphylococcus in sixty-seven cases; pneumococcus, staphylococcus, and streptococcus, ten cases; pneumococcus and streptococcus in chains, three cases; pneumococcus in chains and *Micrococcus catarrhalis*, one case; staphylococcus, two cases; staphylococcus and streptococcus in chains in one case; staphylococcus and *Micrococcus catarrhalis*, two cases.

Friel reports three cases in which autogenous vaccines were used successfully. Blessing isolated three types of staphylococci, *Diplococcus lanceolatus*, and *Streptococcus longus*. Leary states that Vincent's fusiform bacillus is present almost constantly, and he apparently thinks this organism a cause of pyorrhea, if not the specific cause. It may be true that *Bacillus fusiformis* is related to pyorrhea etiologically, at times it may be the chief cause, but the successful treatment of patients by autogenous vaccines in which it is not present would seem to show that if it has any rôle at all it is of minor importance.

Cummins calls attention to a number of systemic conditions which are the result of oral sepsis. In some cases extractions were done. No cultural methods are given; there is simply a statement that vaccines were used for treatment. Collins reports treating three cases of pyorrhea with a vaccine of *Streptococcus viridans*. Godby (1911, 1912) has devoted considerable attention to the relation between diseases of the mouth and rheumatism and rheumatoid arthritis and various other dacrrias. His conclusions coincide with the earlier deductions of Hunter and the later observations of other writers. In 1900 and again in 1911, Hunter attributed to mouth infections, systemic conditions ranging from a simple gastric disturbance to toxic neuritis and even pernicious anemia. Daland and Merritt have called attention to the relation between systemic disease and mouth infections.

Merritt's opinion is that one of the principal things necessary in the treatment of pyorrhea is to see that the defensive or protective substances of the body are brought into contact with the bacteria; otherwise we can expect little permanent result from the use of any systemic measures.

Lindsay reported 172 cases of rheumatoid arthritis, about 8.5 per cent. of which had pyorrhea. Lambert reported 190 cases of rheumatoid arthritis, in seventy-six per cent. of which the teeth were decayed or had dropped out as a result of advanced pyorrhea. Fitzgerald apparently thinks that the tissue changes associated with advanced pyorrhea are due to the streptococcus.

**TECHNIC AND CULTURAL METHODS.**

My technic and cultural methods are the following: The material for bacteriological examination was collected from the pyorrheal pocket by the method of Dr. Joseph Head. That is, after thorough cleansing around the gingival margin, a thin, spear shaped platinum instrument was heated to reduce and while still hot was run up alongside of the root into the pocket. This was then streaked on the surface of slanted blood agar in test tubes. These blood agar cultures were taken to the laboratory as soon as possible. As much of the material as could be removed from the culture medium was then, by means of a sterile platinum loop, carried to a blood agar plate. This was then spread by
means of a sterile glass rod or spatula, as suggested by Hitchens. Without reinoculation this spatula was carried to three plates in succession so that the organisms were well distributed, thus facilitating the fishing of single colonies. I draw attention to this spatula because it can be put into a large test tube and sterilized, whereas the ordinary rod bent at right angles must be heated and is exposed while cooling. After twenty-four hours in the incubator at 37.5° C. the fishings were made; these were likewise made to blood agar slants. After twenty-four hours' incubation, slides stained by Gram's method were studied microscopically. When indicated, other stains were also used. If necessary for further identification of streptococci and pneumococci, serum dextrose bouillon cultures and animal inoculations were made. The Gram negative bacilli, with the exception of those which would grow on blood agar only, were inoculated into fermentation tubes of bouillon containing various carbohydrates for gas production. Bacilli were studied for motility in hanging drops. With a few exceptions all organisms isolated were used in the vaccine.

In nearly all the studies reported by other workers plain agar, bouillon, and Loeffler's blood serum mixture were the only culture media used. It is not strange that the results in even the most serious work are scarcely comparable. It is noteworthy, for instance, that Goadby, who used plain agar, isolated the pneumococcus but five times in seventy cases, while Beebe found this organism in all of twenty cases, and Medalia found it in ninety per cent of 115 cases. None of the three writers mentions the hemophilic bacilli of which Bacillus influenza is a representative.

It is probably premature to insist on a standard method for the isolation of the infecting bacteria from pyorrheal pockets. It is not, however, premature to insist on the use of a medium which will offer conditions favorable to the growth of the greatest possible variety of pathogenic bacteria, a medium at least equal in this regard to nutrient agar containing red blood corpuscles. I believe that blood agar is the best medium for isolation, but for certain microorganisms a modified medium and special technic may be necessary. If evidence

is obtained to demonstrate the pathogenicity of Bacillus fusiformis in pyorrhea, the proper methods for its isolation must be used. It is my intention in continuing this work to study the anaerobic bacteria by the necessary special methods. This has not been done so far.

The question of selecting the proper bacteria from those isolated in a given case is one susceptible, at this stage in our knowledge, of endless discussion. A definite and final decision cannot now be rendered. Some have started out with the preconceived idea that the cocci only are pathogenic. They have discarded the bacilli present without further consideration. Goadby and others have attempted to pick out the bacteria responsible for the infection by a determination of the osmotic indices to the germs isolated. More recently the comple-
nent fixation test has been suggested for the same purpose. Such investigations may be of great scientific interest, but I must question their practical value. Besides increasing out of all proportion the labor required for the preparation of the vaccine, I believe the chances for error both in technic and in interpreting the result obtained are so great that one may not safely eliminate any organism present in the specimen. We believe it is better to make a vaccine containing all the different types found, discarding only those obviously nonpathogenic or sporogenic bacteria. The vaccines used in the series of cases reported by Doctor Head were made in accordance with this belief. The excellent results obtained are submitted as justification for the procedure followed.

PREPARATION OF VACCINES.

The method of preparation of the autogenous vaccines for these cases was similar to that followed in the laboratory for making stock vaccines. The organisms were grown on suitable culture media, ordinary agar sufficing for the most of them; in the case of hemophilic organisms blood agar, of course, was used. After twenty-four hours in the incubator at 37.5° C., the growth was washed from the surface of the agar with normal saline solution. The suspension was removed and thoroughly shaken to break up clumps. After the withdrawal of a small portion for counting, the suspension was heated to 60° C. for one hour. Wright’s method was used for counting the bacteria. After the count had been made, the heavy suspension was diluted with normal saline solution to give the desired number of bacteria in each cubic centimetre. To this dilution was then added 0.25 per cent. tricine-sol. To be certain of its sterility a small quantity of the finished product was planted in fermentation tubes containing freshly sterilized dextrose bouillon. These check cultures were incubated for five days. In addition to this, each vaccine was tested for freedom from any toxic or other harmful substance by the injection of at least one c. c. subcutaneously into a guineapig. This test is used particularly to demonstrate the absence of tetanus toxin or the bacillus of tetanus. The guineapigs were kept under observation for fourteen days.

On completion of the tests the vaccine was put into a twenty c. c. vial with a soft rubber cap over it like those used by Wright. Some of the more recent vaccines were put into syringes of one c. c. capacity with a printed graduated label which facilitated the use of fractions of a cubic centimetre.

The suspensions of bacteria were so diluted that they contained the various organisms isolated in the following proportions:

Staphylococci .................................. 300 million per c. c.
All other organisms ............................... 50 million per c. c.

The accompanying tables show in detail the results of the bacteriological study of the cases. Figures preceding + sign indicates where more than one type of that organism was present.

Diplococci noted above had very much the same appearance on blood agar as the pneumococcus, excepting that the colonies were smaller. They were replated several times and remained true to type. Serum bouillon cultures showed only cocci in pairs and were not pathogenic. I was unable to demonstrate capsules on organisms present in fluid withdrawn from mice several hours after intraperitoneal inoculation. The bacillus noted in the last column was of the milk fermenting type. It would not have been possible to differentiate the several types of streptococci without blood agar and most painstaking and careful study of colony formation, with a lens, using direct white artificial light.

**PNEUMOCOCCUS.**

The strains 8, 10, 18, 19, 20, 23, 28, 36, and 46 were inoculated into mice and the capsule was demon stratred, Hiss capsule strain being used. The remaining cultures noted in Table 1 were all of this same type, but were lost before animal inoculations could be made.

The strains in the first column were replated on blood agar. They changed somewhat, becoming pinpoint in size without special characteristics. We can attribute this only to symbiosis. Following the same plan regarding those in column four, they lost their hemolytic character, but retained somewhat their irregular granular characteristics. The other two did not change their characteristics.

Those in the first, second, and fourth columns were short Gram negative bacilli with many threadlike forms, while those in the third column were identical with *Bacillus influenzae*.

L. liquefied; NL, not liquefied; NG, no growth; * , grows poorly on plain agar; no gas produced; + , gas produced; B, bubble; O, nonmotile; A, actively motile; S, sluggishly motile; M, moderately motile.

CONCLUSIONS.

1. While a large number of organisms have been isolated in this series, we are unable to attribute to any one of them an etiological rôle in pyorrhoea alveolaris.

2. The use of plain or serum agar, plain or serum bouillon, or Loeffler's blood serum mixture are not the best culture media for studying diseases of the mouth and of the respiratory passages.

3. Blood agar is the best culture medium known to us at present for work of this kind because the hemolytic bacteria grow only upon this medium: in addition to this a number of types of streptococci can be differentiated at once, by the appearance of the colony, studied with a lens—using direct artificial light.

4. A vaccine for the treatment of pyorrhoea should contain all the organisms isolated in a given case.

5. Before drawing final conclusions, a study of the possible association and rôle of anaerobic bacteria is necessary.

THIRTY-THIRD AND DIAMOND STREETS.

THE MECHANOTHERAPEUTICS OF ACUTE CROUPOUS PNEUMONIA.

BY EDGAR F. CYRIAX, M. D.,

Historical note.—In 1847 an attempt was made by Branting (1) to treat acute pneumonia by means of manipulations; he appears, however, only to have employed those forms known as arm vibration and chest lift shaking. During subsequent years no systematic plan of treatment was worked out to deal with the condition specified—indeed not even an effort was made to repeat Branting's first steps —until at last during the early seventies Henrik Kellgren systematized his methods of combating the disease. These, however, have hitherto hardly found any acceptance; in fact, any reference to them almost invariably leads the author (2) to state that any form of manual manipulation for such conditions as acute pneumonia is most strongly to be condemned. Whether this is in general argued from theoretical grounds or from actual failure after repeated attempts, it is impossible to say. During the early seventies Henrik Kellgren, as already intimated, had been employing his special methods with success, and his efforts were mentioned about this time by both Wretlind (3) and Glatter (4): Wretlind (5), who learned the modus operandi, was able at a later date to test its efficacy himself. In 1890 Arvid Kellgren spoke with confidence of the success that he and his brother had achieved (6). A very brief account of the methods employed was published by Möller (7) in 1900, and a somewhat more detailed one by the author (8) of this paper in 1903. Otherwise medical literature on the subject is conspicuous by its absence, and
this is the author's reason for further enlarging on the subject.

CERTAIN POINTS IN THE PATHOLOGY AND SYMPTOMATOLOGY OF ACUTE CROUPOUS PNEUMONIA.

Those points need consideration in view of what follows. As is well known, the onset of the disease is fairly sudden, the respiratory change coming on early. The respiratory act very soon becomes quick, shallow, and labored. The cause of this respiratory distress has been variously ascribed to pain, fever, loss of part of the pulmonary function, nervous elements, circulatory disturbances, etc. To my mind by far the most important cause—and the one which hitherto has escaped recognition—is reflex contraction of certain of the muscles of respiration, this reflex contraction being in the majority of cases aggravated by such direct causes as spread of inflammation, toxaemia, venous and lymph stasis, etc. The contractions as a rule come on fairly early (sometimes almost immediately), and tend to become more marked during the course of the disease; then, according to whether the disease terminates by crisis or lysis, they disappear either rapidly or slowly.

The reservation must be made that not all cases of pneumonia exhibit these muscular contractions, and those that do not are the least severe and least dangerous ones. Indeed the severity of the disease is, ceteris paribus, proportional to the amount of muscular contraction.

In many cases these muscular contractions are among the first symptoms, and they may become firmly established before even the most careful examination can detect anything wrong with the lung itself. This early arising of the contractions is analogous to the same phenomena as regards the abdominal organs.

In 1903 I wrote (9): "In the abdomen reflex contractions of the muscles of its wall are frequently found as a result of irritative or inflamed conditions of organs in its cavity. The same state of matters obtains with the thorax; reflex contractions of the intercostal muscles result from many morbid conditions of the lungs, bronchi and pleura." In the course of the description of the treatment of acute croupous pneumonia, I stated (10): "The impediments to respiration that lie in the muscular apparatus are found to be: Contractions in the intercostal muscles over the affected lobe or lobes, deficient action of the diaphragm, with or without marked contraction of the abdominal muscles." These various remarks seem, however, to have passed almost unnoticed, but more recently a certain amount of independent work has been done with regard to the reflex contractions arising in thoracic disease, especially with regard to phthisis pulmonum and pleurisy. The name of Pottenger (11) is generally associated with the former, the name of Ramond (12) with the latter. One or two authors have also studied the arising of reflex contractions in acute croupous pneumonia, but only as regards one or other group of muscles; no one has drawn the clinical picture of the muscle contractions as a whole.

In the next place it is necessary to enter into certain details concerning the site and extent of these contractions, and the deductions to be drawn therefrom. These contractions may occur in the following muscles: 1. Intercostals; 2. diaphragm; 3. erector spine; 4. anterior abdominal muscles; 5. cervical muscles; 6. pectorals; 7. serratus magnus; and, 8. various others.

1. Intercostals.—The intercostal muscles that lie over the affected lobe or lobes are nearly always contracted in the whole of their length. This is not always the case in deep seated pneumonias, but always when the inflammation has reached the surface. In severe cases of pleuroneumonia the contraction in the intercostal muscles may be observed to extend either above or below the affected pneumatic area, and when the lower intercostal muscles are affected, the corresponding anterior abdominal muscles are generally also contracted. Part of the contraction in the intercostal muscles is in all probability due to the fact that when the inflammation has reached the surface, pleurisy is present to a greater or less extent. The intimate connection between the blood, lymph, and nerve supply of the pleura and intercostal muscles readily accounts for the facility with which intercostal muscle contraction arises in cases of pleurisy; the author in a recent article (13) on the Mechanotherapeutics of Acute Pleurisy has emphasized these points. Myositis of the intercostal muscles has been noted by several authors (14).

2. Diaphragm.—The contraction may be unilateral, the half on the affected side being involved, or bilateral. There is seldom complete bilateral immobility: when there is, the case, unless this contraction is removed or alleviated, almost always proves fatal. Litten's phenomenon has been noted to be absent on the affected side in pneumonia and the diminished excursion of the diaphragm on one or both sides has been frequently demonstrated by means of the x-rays. In connection with this, it is of interest to note that diminished movements of the diaphragm have been found to be an early sign of phthisis (15).

This diminution of movement may be aggravated directly through myositis (16) arising in the muscle, by extension of the inflammation from an involvement of the diaphragmatic pleura, or from irritation of the phrenic nerve either reflexly or directly. I have seen marked fixation of the diaphragm in cases of apical pneumonia. Other causes may be attempts of the muscle to provide a support for the consolidated portion (whose weight is greatly increased), or temporary loss of contractility and expansibility of the lung.

The chief causes of the contraction appear to be reflex. It has been established that irritation of the intercostal nerves can readily cause contraction in the diaphragm. Hess' diaphragm reflex (17) is the result of light percussion of the nipple; Wallein (18) found that it also resulted from irritation of the skin in the nipple line or between the third to sixth ribs, or in the axilla. Quadrone (19) found this reflex present in seventy-five per cent. of all cases; it is absent in locomotor ataxia and allied conditions (20). A large number of reflexes (21) through the phrenic nerves are said to occur; according to Capps (22), these nerves are sensory to the anterior two thirds of the diaphragmatic pleura.

3. Erector spine.—There is nearly always contraction in the segments whose nerves of supply
correspond to the anterior roots that supply the intercostal spaces over the pneumatic area, and the contractions in the former seem to follow very closely those in the latter. In pneumonia of the lower lobe the contraction sometimes extends downward to the sacrum—lymph stasis in the gutal region has been described in cases of pneumonia (224), but it rarely extends above the upper limit of the pneumatic area. These contractions may be due more to the presence of pleurisy than the pneumonia. Ramond (12) found erector spine contractions in ninety-four per cent. of all pleurisy. Romolo (23) found that the arising of an exudation in the pleura in cases of pneumonia removed them.

4. Anterior abdominal muscles.—These are frequently involved, especially when the lower intercostal muscles are contracted, but less commonly in apical pneumonia. The contractions may be unilateral or bilateral and may involve chiefly the recti or be more general. They may be very severe—a case has been recorded in which they only yielded to chloroform narcosis (24)—and may either persist throughout the respiratory phase, or relax between each inspiration. Hoffman (25) found, as a result of experimental investigation, that abdominal rigidity is a reflex arising through the intercostal and lumbar nerves, and can arise from irritation at any point in their course. It can also arise in cases of pleurisy through irradiation, but in cases of pneumonia only when the parietal pleura is affected by toxemia, etc. Glajsenfeld (26) regards the abdominal rigidity as due to irritation of the sympathetic, Hampeln (27) as caused by involvement of the vagus and sympathetic, while Franke (28) considers it to ensue from lymphatic involvement.

5. Cervical muscles.—These are often contracted in cases of apical pneumonia, less frequently in pneumonia of the lower lobe. Such contractions must not be confounded with the rhythmical contractions of these muscles in their capacity as extraordinary muscles of respiration in consequence of dyspnea. In connection with this, it is of interest to note that Pottenger found contraction in the scaleni of one side in the case of an acute tuberculous lung.

6. Pectoral muscles.—Contraction or irritability of these muscles is a fairly early sign: this is similar to what occurs in phthisis pulmonum (28).

7. Serratus magnus.—This muscle appears to be contracted in some cases, thereby pulling the shoulders forward; the pectorals may assist it. Probably the cause is irritation of the lateral branches of the intercostal nerves, although in cases of apical pneumonia it is possible that the lower roots of the long thoracic nerve may be affected.

8. Various other muscles, such as the posterior scapular, subclavii, trapezius, etc.—These may also be affected, but are not sufficiently important to need more than passing mention.

THE EFFECTS OF THE PERSISTENT MUSCULAR CONTRACTIONS.

This will now be considered. Viewed as a whole, it is a limitation to a greater or less extent of the respiratory movement. Considered more in detail:

1. Gaseous interchange in the lung.—The greater the muscular contraction, the greater the fixation of the thorax and the smaller the amplitude of the respiratory movement (29). The acceleration of respiration only to a certain extent compensates for the diminution in depth. This is easily tested even in health; a series of rapid but shallow respirations is insufficient, and it soon becomes necessary to take a deep breath in order to remove the feeling of impending suffocation. With regard to pneumonia it must be remembered that a respiratory rate of fifty is common, and that even in nonfatal cases from sixty to seventy may be reached; thus the patient suffers from an insufficient intake of oxygen and an inadequate elimination of carbonic acid.

2. Venous return to the heart.—In consequence of the diminished respiratory movement, the ordinary mechanism by which inspiration tends to cause a negative pressure in the veins—expiration the opposite—is rendered much less efficient. Venous stasis results not only in the inferior and superior vena cava, but also in the pulmonary veins. As a result there is venous congestion around the air vesicles, and this tends to reduce the proper oxidation of the blood.

3. Blood.—The blood tends to become venous partly from the stasis in the large veins, partly from the diminished intake of oxygen, and partly from the diminished output of carbonic dioxide (30). The last factor has a further deleterious effect upon the circulation rate, as the excess of carbon dioxide causes the blood to become more viscous and increases its tendency to coagulate. It must be remembered that even in the early stages of an attack of acute pneumonia, venesection may bring to view a flow of tarry dark venous blood.

4. Heart.—The heart's work is increased, because: (a) It endeavors to replace the loss of the venous suction and force pump consequent upon the diminished movements of the chest wall; (b) there is greater resistance in the lung generally, due to the venous stasis and blocking of the pulmonary capillaries; (c) there is increased viscosity of the blood; and (d) there is insufficient oxygen and too much carbon dioxide in the nutrient blood in the coronary arteries.

5. Pleura.—When pleurisy is present (as almost always) there ensues practically a complete and persistent cessation of the local respiratory movements. This causes not only a complete cessation of the activity of the pleurolymphatic respiratory pump, but as a consequence causes in the muscles themselves a partial, if not complete, cessation of their own lymph flow, together with a very considerable amount of local venous stasis. Further, the arterial circulation in the pleura is impaired, and in addition the irritation of the intercostal and diaaphragmatic nerves tends to aggravate the pain.

6. Other effects.—These may be summarized as follows: Venous congestion and lymphatic stasis in the abdomen, and frequently distention in that cavity; impediment to the circulation, arterial and venous, in the muscles of respiration themselves and inflammation will therefore more readily ensue in them. This will of course aggravate the pain already present from the persistent contraction, and so cause greater immobility of the muscles.
From these considerations it is obvious how prejudicial and dangerous a factor is this contraction of the respiratory muscles. And the consequences are still further aggravated by the fact that throughout the solid lung the circulation is practically at a standstill, and this in itself embarrasses the heart's action.

THE MANUAL TREATMENT APPLICABLE TO THE DISEASE IN QUESTION.

The objects of the manual treatment are as follows: 1. Diminution of the muscular contraction; 2. diminution of the inflammation in the pneumatic area, and promotion of the circulation throughout it; 3. diminution of the inflammation in the pleura and promotion of the circulation through it; 4. stimulation of the nervous elements of the lungs; 5. increase of the respiratory movements, the combined result of the foregoing; and, 6. improvement of the constitutional powers as a whole.

The manipulations and exercises employed are as follows:

1. Vibrations. I have on several occasions described (31) the modus operandi so it is here but necessary to add that they should only be generated through incomplete tetanus of some of the muscles of the forearm, and not through complete tetanus of most of the muscles of the upper extremity—a mistake, I regret to say, that is frequently made. The correct method of executing vibrations is not musculely tiring; it enables the operator to apply them evenly, gently, and continuously for as long as may be necessary. Vibrations may be stationary or running.

A.—Stationary vibrations. The operator sits at the side of the patient; let it be presumed for the sake of illustration that the left lung is affected and that the operator is seated at the right of the patient. One of the following positions may be selected:

(a) The operator passes his left hand between the patient and the bed, and places the last phalanges of his fingers which are somewhat separated over the most affected portions of the erector spine; he then places the separated fingers of the right hand over the most contracted intercostal spaces. This is employed chiefly for basal pneumonia and the concomitant pleurisy.

(b) The operator passes his left hand between the patient and the bed, and places the palmar aspect of his fingers, which are separated, on the interscapular region; his other hand he places over the corresponding anterior portion of the chest. This position is employed chiefly for general vibration of the chest, double pneumonia, or as a method of applying vibrations to the heart.

(c) This is the same as (b), but the operator places one of his hands posteriorly over the scapular region of one side, his other hand over the corresponding anterior aspect of that side of the chest. This is employed chiefly for apical pneumonia.

The results of these vibrations are:

(a) Removal of or diminution in the amount of the contraction in the intercostal muscles, erector spine, diaphragm, and anterior abdominal muscles. According to the position of the operator's hands, so will the upper or lower muscles be particularly influenced. Coincident with the removal of the contraction is the diminution of venous and lymph congestion in the muscles themselves, and the promotion of the venous and lymphatic circulation therein. This reduces the pain, still further enabling the muscles to work rhythmically in order to re-establish the movements of respiration.

(b) Absorption of the exudation and inflammatory material in the inflamed lung, and promotion of the venous and lymphatic flow therein. The fact that vibrations favor the absorption of chronic exudations has long been recognized, although but few observations have been published as regards acute exudations. I have repeatedly found that such acute exudations in synovial membranes, tendon sheaths, pleura, and peritoneum can be made to undergo absorption by means of vibrations in a very short space of time (31). In pneumonia the difference in the auscultatory phenomena before and after vibration of the lung show that the affected part of the lung has become less solid and that freer ventilation is taking place in it.

(c) Absorption of the exudate and lymph deposits in the pleura, and improvement in the pleurisy. The reader is referred to a recent article by the author (13) on the subject of the Mechanotherapeutics of Acute Pleurisy.

(d) Diminution of pain. This is partly due to the direct analgesic action of the vibrations, and partly to other factors, such as reduction of the muscular contractions, promotion of the circulation, diminution of the inflammation, etc.

(e) The gaseous interchange in the lungs is promoted. A certain amount of experimental work has been done in connection with this which supports this fact as ascertained clinically. Von Marxow (32) set up the theory that the minute shocks (vibrations) imparted to the cells of the lungs by the heart beat were necessary for the gaseous interchange, that they were indeed sine qua non for actual existence. Other observers have concurred in this. Buttersack (33) concluded that the vibration of the blood in the arteries was a very important factor in this connection. Buchheim (34) considered that the vibration of the blood in the aorta stimulated the cardiac nerves.

(f) Increase in the amount of expectoration, which is ejected with greater ease and less pain, and is frequently seen to be less viscous than before.

(g) Sedative effect on the cardiac action; a reduction of ten beats a minute is frequently found after thorax vibration. This results partly through the medium of the cutaneous nerves and partly through direct effect on the heart muscle. The sedative effect of heart vibration on the cardiac action has been studied in a large number of diseases, although acute forms of disease have hitherto received very little attention. As the result of many hundreds of observations I can assert confidently that the beneficial effects of heart vibration on the cardiac action in acute diseases is as marked as in the majority of chronic ones, if not more so.

B. Running vibrations. (a) These are executed slowly along the intercostal spaces in a direction from before backward. Generally one space is treated at a time, the operator using his approximated forefinger and thumb; if two or three spaces
are treated simultaneously the tips of the fingers are used. The general effects of these are the same as those obtained from stationary vibrations. Their special effects are the promotion of the venous and lymph return in the intercostal spaces and the pleura (the intimate connection between their respective vessels must be borne in mind). (b) Side shaking: This movement is often wrongly carried out, and I shall therefore describe its technic. The operator, standing in front of the patient, places his hands laterally against the patient's lower ribs, one at each side. Continually drawing the ribs slightly forward, he executes an intermittent series of soft elastic pressures downward, inward, and forward. The elbow joints must be kept fairly well extended, and the movement is generated chiefly from the shoulder joint through alternate movements of abduction and adduction. Beginners are often seen to carry out this movement, keeping their elbow joints flexed to a right angle, the hands being considerably dorsiflexed; the movement becomes in consequence jerky and irritating, and would probably do harm in a case of pneumonia. Care must be taken during each relaxation not to move the hands relatively to the patient's thorax; they must maintain their close contact and identity of position throughout.

The effects of this side shaking are: (a) A pumping of air in and out of the lungs, especially the lower part. This is of special value in basal pneumonia. Auscultation before and after side shaking in these cases often demonstrates that better ventilation has been induced.

(b) Promotion of the circulation in the lungs, especially in the lower part, through the alternate application and removal of pressure.

(c) Promotion of the lymphatic return in the same. This is of especial value in reducing the inflammation in the affected area.

(d) Diminution of the amount of contraction in the intercostal muscles, anterior abdominal muscles and diaphragm, with promotion of their circulation, reduction of the virulence of any inflammation therein, and consequently a diminution of the pain. All these tend to reestablish the movements of respiration.

(e) Improvement in the pleurisy.

(f) Sedative effect on the cardiac action.

3. Active respirations. The average practitioner would, I imagine, at once urge that under the circumstances they were impossible on account of the intense pain caused, and dangerous because they would irritate the inflamed pleural surfaces by making them rub against each other; also that every form of exertion on the part of the patient should be strictly avoided as dangerous. When, however, the preliminary vibrations and side shakings have reduced the muscular spasms, the inflammation, the pain, etc., as already made clear, it is found that the patient can take deep inspirations and expirations with but little pain—indeed any pain which arises with the first inspiration diminishes or even quite disappears when a few more have been taken. It is often advisable to assist the patient’s active efforts at respiration by simultaneous passive manipulations, generally in the form of side shaking, or pressure upon the abdomen during expiration. This greatly aids the patient’s efforts and renders possible much deeper respirations. Moreover, the effect on the circulation and gaseous interchange in the lungs is much more marked. If it be found that a definitely localizable pain is the cause of the patient being unable to take a deep respiration, a short vibration specially applied generally removes it, and enables such respiration to take place with ease. The patient being thus rendered to take deep respirations, the beneficial results on the circulation of both blood and lymph in the lungs, pleura, and heart itself, are too obvious to need more than mention; their importance can hardly be overestimated.

4. Subdiaphragmatic suction. The movement, which it is best to term thus, is carried out as follows: The operator places the tips of his fingers and thumb, or the tips of his fingers alone, in the subcostal angle below the xiphisternum. Applying a certain amount of pressure meanwhile, he then moves them in unison with that part of the skin of the abdomen with which they are in contact at a fairly slow rate downward; after which, relaxing the pressure, he brings them back to their original position. The movement is repeated several times in succession. The effect of the movement is to relieve the contraction of the diaphragm; this can often be induced in a most striking manner.

The immediate effects on the respiratory act of these local lung manipulations are often quite marked. The patient himself feels a relief which no other method, as far as I know, can afford; the respiratory movements are less labored—the movements of the aie nail can sometimes be seen to cease—and becomes slower and deeper; the cyanosis is reduced in amount. Besides this, quiet sleep often supervenes immediately—another very desirable result.

5. Frictions on the posterior divisions of the spinal and on the intercostal nerves. The technique of nerve frictions has been described elsewhere (35). The effects are: (a) Momentary contraction of the corresponding erector spinae and intercostal muscles, possibly to some extent of the anterior abdominal muscles and diaphragm, with subsequent greater relaxation; (b) stimulation of the sensory elements of the lungs and pleura, with resultant stimulation of the excitoreflex of repair. The action is analogous to that of a mustard plaster placed between the shoulders for bronchitis; (c) vasovascular phenomena probably play a part; (d) transient dilatation of the lung (probably)—the so called reflex of Abrams; there seem to be no records of investigation as to whether this reflex is induced in pneumonia, but it certainly seems to occur in healthy lungs, and by temporary relief of the tension it would help in promoting the circulation; (e) as regards the fourth and fifth left dorsal nerves, a stimulatory effect on the heart; (f) as regards the eighth and ninth left dorsal nerves, a stimulatory effect on the spleen; (g) as regards the tenth and eleventh dorsal nerves, a stimulatory effect on the kidneys; and (h) leucocytosis.

6. Abdominal pettissage, including frictions on the kidneys. The modus operandi I have described on several occasions (36); the reader is referred to the original articles. Neither is it necessary to detail the effects of the manipulations comprised under this

CEREBROSPINAL FLUID AND ITS DIAGNOSTIC SIGNIFICANCE.*

By Abraham I. Rubenstone, M.D.,

Philadelphia,

Pathologist, Mount Sinai Hospital.

I wish to discuss primarily the manner of production of cerebrospinal fluid, its circulation in the cranial cavity, and the factors determining its amount. The first thing that I should like to emphasize is that cerebrospinal fluid is a secretion, not an exudate, transudate, nor lymph. This has been recently established by the investigations of Haynes and Kopetsky, as well as foreign observers, and the assertion that the cerebrospinal cavity is one large lymph space is now generally refuted. The blood supply to the brain, through the arrangement from the circle of Willis, is always abundant; especially it is so at the choroid plexus of arteries, the return circulation being amply taken care of by the cerebral veins which empty into the great venous sinuses. I repeat that cerebrospinal fluid is a true secretion furnished by the gland-like cells of the ependyma, which surround the choroid plexus, for upon this phenomenon will largely depend the manner of treatment in affections of the cranial cavity.

The amount of fluid constantly present is, according to Howell's conservative estimate, about sixty to eighty c. c. It courses from the choroid plexus into the lateral ventricle through the foramem of Monro into the third ventricle, thence through the aqueduct of Sylvius into the fourth ventricle and through the foramen of Majendie into the great subarachnoid space. After filling the spinal canal it courses upward over the brain to enter the superior longitudinal sinus. Rarely is any carried away by the lymphatics. When the Pacchionian bodies are fully developed after the third year they transfer the spinal fluid to the sinus. Since the pressure in the arteries is always above that in the sinuses, and since the pressure of the spinal fluid is below that of the arteries and slightly higher than

*Read before the Southeast Branch of Philadelphia County Medical Society, October 17, 1913.
in the sinuses, you can readily understand why the fluid does not change as rapidly as those fluids that have a driving force behind them, as it entirely depends on slight difference of pressure, so that as slowly as it is secreted so is it eliminated. This is a wonderful contrivance of Nature to avert sudden changes in intracranial tension, so that normally, although the blood pressure can oscillate to some degree during sudden changes of posture and emotion or slight cranial trauma, yet the intracranial tension does not vary to as great an extent, owing to this slow circulation of spinal fluid. This rather meagre communication of cerebrospinal fluid, however, and direct arterial supply of blood becomes a disadvantage during the progress of abnormal conditions, for under such circumstances toxic products are very slowly eliminated, and what is even more important, the all neutralizing elements of the blood stream are not brought into actual contact with the bacteria and their toxins that flourish in an ideal culture medium.

What are the constituents of normal cerebrospinal fluid in so far as they interest us by their variation in disease? Normally it is a clear, crystalline, colorless fluid. It may have a slight yellowish tinge due to leucin in the pigment of blood serum. Although it is usually slightly alkaline, it may be very faintly acid due to an increased lactic acid content. Its specific gravity varies between 1.005 and 1.010, and as low as 1.003 has been noted normally. Under normal conditions no more than six cells to the c. mm. has been found, and these usually are lymphocytes with an occasional endothelial cell. The chemical substances found which interest us are, first, a reducing substance to the extent of 0.04 to 0.05 per cent. It reduces copper (Fehling’s solution) but not bismuth, does not ferment nor give o-sazon with phenylhydrizin. Although such men as Halliburton and Coriat are in dispute as to whether it is sugar or a body similar to pyrocatechin, suffice it to say that in all normal states it is present if carefully sought for. The proteids found are globulin, nucleoprotein, and protalbumose, all in small amounts never over 0.25 gram to the litre. Serum albumin is rarely present.

Let us consider the changes that are produced in this fluid when bacteria gain entrance into it and begin to multiply. Soon after infection cerebrospinal fluid, due to irritation of the meninges and cerebrum, becomes of higher specific gravity owing to increased globulin, which is the result of bacterial destruction and exudation from the surrounding tissues. Until this increase of globulin occurs, the intracranial pressure remains unaltered, but soon the secreting ependyma attempts to dilute the fluid and the outpouring of fluid becomes greater. It therefore follows that the clinical manifestations of cerebral irritation occur some time after the infection has gained headway.

Noguchi, when he announced his butyric acid test, removed the obstacle, in diagnosing slight increase of globulin encountered in the ordinary rough nitric acid and acetoferricyanide tests. This test has proved itself highly efficient in determining meningial inflammation in its earliest stage. No matter what the infecting organism may be, the Noguchi test is always present in the earliest stage of meningitis and before the fluid has become visibly turbid. At this stage, also, the fluid will show an increased number of cells, usually of the polymuclear variety. However, in such conditions as severe intestinal auto-intoxication, pneumonia, and typhoid fever, the globulin reaction may be positive, but these conditions may be differentiated from a true meningitis, in that in the latter the cellular elements are always greatly increased, and the reducing substance is usually absent. The cellular elements at this stage of meningitis do not aid us in differentiating the variety of meningitis. Even in the late stage of tuberculous meningitis, although there is said to be a mononucleosis, we have found this true only in three of our six cases studied within the past year. In tuberculous meningitis and acute poliomyelitis the reducing substance never disappears. Our conclusions have been confirmed by a vast number of cases studied by Jacobs, as well as Blatties and Lederer.

Now we come to the all important phase in the consideration of cerebrospinal fluid, namely, the diagnosis, especially, as we will all agree, the early diagnosis of acute supplicative meningitis before its classical clinical symptoms and signs become evident. The question here might arise, when should the physician decide to do a lumbar puncture in a case of obscure physical signs when the patient presents a rising temperature? We hold that the physician is more than justified in performing a lumbar puncture when the blood count shows a leucocytosis with a relatively high polymucleosis; when he can exclude acute suppuration of the ear and throat, when the chest and abdominal signs and symptoms are wanting, and when, if possible to obtain it, the urine shows no purulent inflammation along the genitourinary tract; or, in other words, in a case of obscure fever with a high polynuclear blood count.

Let us assume that two days pass after the onset of the rise of temperature, in an average case, before the physician can exclude the ordinary causes of this febrile condition. If at this time a lumbar puncture is performed and a blood-free spinal fluid is obtained, we shall probably find, assuming the case is that of an early meningitis, that the fluid has lost its clear brilliancy, that upon centrifugation the cellular elements are greatly increased and consist nearly all of poly-nuclear cells; we also find two chemical tests that are of great significance. You will remember that it is now an established fact that no matter how early in a case of supplicative meningitis, the Noguchi butyric acid test will be strongly positive and the reducing substance usually absent. Under such conditions we have narrowed down, by elimination, the diagnosis to the ordinary pyogenic bacterial infections, namely, meningococcus, pneumococcus, streptococcus, staphylococcus, influenza, or typhoid meningitis. We know that all these forms of meningitis, excepting the meningococcus form, are uniformly fatal. The results attained with Flexner’s specific therapy, we believe depend entirely on how soon we can apply it to the affection.

If, then, you establish a diagnosis of acute meningial inflammation when the sediment in the spinal fluid contains few of the organisms and when they are with difficulty found or not found at all, what chances are you taking in injecting the only specific
It may add that, although I have scanned the literature, no one has yet, I believe, reported this reaction. In those epileptics in whom we find a short coagulation time of blood, this finding, therefore, explains the increase in the coagulation time of blood after hypodermic injections of spinal fluid from one epileptic into another.

Conclusions.

Now as to conclusions, as far as treatment is concerned in infections of the cerebrospinal canal, since spinal fluid is a secretion, drugs therefore, which are introduced into the system, other than directly into the cerebrospinal canal, would not reach it unless the glands which secrete the spinal fluid have a positive chemiotaxis for that particular remedy and secrete it, thus bringing it into actual contact with the diseased area. A drug that seems to find favor with the ependymal cells is hexamethylenamine, and it therefore appears in the spinal fluid as formaldehyde. On the other hand, Cramp and others failed repeatedly to recover arsenic in the spinal fluid after salvarsan given intravenously. Recently, investigators have found that of all antitoxins, none are eliminated through the spinal fluid. This explains why only recently Noguchi and Moore found Spirocheta pallida in the lower layers of the brain cortex, but not in the walls of the blood-vessels supplying these areas; and even more recently puncture of the brain in live paralytics and injection of this substance into rabbits actually caused syphilitic lesions in these animals.

It is therefore evident that in the treatment of cerebrospinal disease, unless we can prove that our remedy will appear in the cerebrospinal fluid, we must introduce it directly into the cerebrospinal canal. As for the dangers of lumbar puncture properly performed, I have yet to see a fatality in any one. If we follow Sophian, who has probably performed more lumbar punctures for treatment than any one in America, if the blood pressure is watched while withdrawing spinal fluid, the dangers of lumbar puncture are practically nil.

PELLAGRA IN MAIN.

By Edwin W. Gehring, M. D.,
Portland, Maine.

As further evidence of what seems to be the pandemic nature of pellagra, I, herewith, report brief histories of three cases of the disease seen in Oxford County, Maine, during the past spring and summer. None of these pellagrins was under my care at the hospital; in fact all were more or less inaccessible, hence the incompleteness of histories and examinations.

Case I. Mrs. R., aged fifty-nine years, was seen in consultation with Dr. H. L. Bartlett, of Norwalk, Maine, on June 26, 1913. She was a feeble little woman who had always lived and was then living in sanitary surroundings. Everything about her home was immaculate. We were unable to get any satisfactory history of past or present illness; suffice it to state that at a comparatively recent date, during the year 1909, she had had a mental disturbance for which she spent some time in the Augusta Hospital for the Insane. Of late, however, she had been living at home and was at the time of our visit entirely rational. Her present illness was said by the attending physician to have begun in January, 1913, and her complaint now was of "sore mouth," painful knees, many burning evacuations.
from the bowels daily, and irritable stomach. The stools often numbered twenty in twenty-four hours. Upon examination was found a much emaciated woman with a somewhat sallow skin, and a symmetrical dark pigmentation. Her face appeared bovine and carried herself with a mala, a mild secondary anemia. There was nothing abnormal in the blood smear. The systolic blood pressure varied from 100 to 105 mm. Hg.; Wassermann test not made. This patient died within one week of her visit to the hospital. The physician, H., discharged her.

Concerning her usual dietary we learned that she was extremely fond of bakers' doughnuts and of uncooked cereals such as shredded wheat.

CASE II. Mrs. B., aged forty-nine years, employee in the stock room of a shoe shop, presented herself in May, 1913, for examination with an infected left palm, which, after free incision, discharged profusely, but incapacitated her for work for seven weeks, when she complained of "sore mouth" and salivation, nausea and diarrhea. Simultaneously, an erythema spread symmetrically from the regions of the styloid processes over the backs of the hands and fingers to the bases of the nails. The dermatitis was sharply demarcated at the wrists and nail bases. Diarrhea also appeared during this same period. The physician, C., retained the patient in the hospital for five weeks. During the same period of time, there was a "chronic poisoning from the absorption of materials used in a shoe shop." During the winter of 1911-1912 these symptoms gradually subsided, although she suffered considerably from pain in ankles and knees. The year 1912 was a very fruitful year.

This patient was also seen with Dr. H. L. Bartlett on September 4, 1913. Up to within two weeks she had considered herself to be in perfect health. Since then there have been "attacks of stomach weakness" with sore mouth and salivation, with the reappearance in both palms of what looked not unlike a dry scaly eczema which did not itch. The patient's general appearance was one of cleanliness and health. Physical examination was negative, also the short lists. Of interest was the patient's diet which included meat in moderation, few vegetables and fruits, no cereals nor grains, bread and butter; also the facts that she had never used cotoline or other vegetable fats, had never been outside of the house that to date no mental disturbance had manifested itself. Since September improvement in all symptoms had been progressive so that when last seen she looked and felt perfectly well.

CASE III. Mrs. F., aged thirty-four years, was first seen by Dr. H. L. Bartlett about the middle of July, 1913, when she complained of having felt tired for five or six months; the appetite, usually good, had during that time been poor and incomplete, and had lost weight, from 110 to 76 pounds.

Family history. Father deceased. One child and age at time of death not known. Mother was living and well; brothers and sisters all living and well.

Past history. Patient had had three children and all were living and well. One had attacks of tonsillitis, but otherwise no illness. Menstrual history negative save that complete cessation of the menses in the late spring of 1913 was the occasion for consulting a physician. She lived in Maine, she had lived ever since on a farm among the mothers of her surroundings many of whom have always been "irritable" and a life long sufferer from periodic attacks of frontal headache. At Doctor Bartlett's first visit, he found a spare woman of medium stature, nothing abnormal, who complained of irregualar appetite, gastric burning sensations, and who exhibited a decided discoloration of the skin, sharply demarcated on both forearms, she was a scapular spine, on the forehead, and nose, which looked very like bad sunburn. At this time there was no diarrhea but marked mental disturbance. About August 1, 1913, two weeks later, the patient was taken to the Hospital for the Insane at Augusta, Maine. While there, diarrhea first made its appearance. For reasons more imaginary than real the husband took his wife home at the expiration of sixteen days, notwithstanding her persistently insane state continued.

I saw this patient with Doctor Bartlett, as a matter of courtesy on his part which I greatly appreciated, on September 4, 1913, in her home, two weeks after her return from the hospital. At that time it was necessary for her to bandage her head and tie her in bed. The face wore a troubled, confused look as the patient lay motionless and speechless. It is doubtful if she recognized anybody. The sites of discoloration now presented a dry, scaly appearance. The deep reflexes were plus, superficial reflexes diminished; the pupils equal and regular, responded slowly to light. Heart, lungs, and abdomen were negative. Cervical, axillary, and inguinal lymph nodes enlarged. Urine normal. Blood pressure was not taken nor blood examination of any kind made. Stools were not examined. Since leaving the hospital the appetite had improved and the diarrhea had been checked. Despite the superlatively healthful country in which this patient lived, her immediate surroundings left much to be desired. It was of interest, and perhaps significant, that cotoline had been used as a substitute for lard in this home for eight or nine years, and that only a minimum amount of sweet corn on the cob was eaten in season. Two of the symmetrical erythematous areas were near parts of the body usually not exposed to the sun's rays—on the scapular spines. Since our joint visit in September the menses had not reappeared themselves nor was there evidence of pregnancy. The bowels moved with normal frequency, and as the result of improved appetite and less weight loss in weight had resulted. Her physician writes under date of November 4, 1913, "she recognizes everyone now but is morose, melancholy, and talks suicide. Although physically strong enough to be about the house and out of doors, she requires constant watching, and will undoubtedly endeavor to commit suicide if an opportunity presents itself."

These cases, together with others recently reported by Lee (1) of Boston and McDonald (2) of the Danvers State Hospital, fail to establish the etiology of the disease, but they confirm the belief, becoming every day more general, that pellagra is not a disease peculiar to tropical regions. These patients had never been out of the State and had lived continuously in Oxford county, where they had been born. All had gastrointestinal symptoms and typical skin lesions, but as yet only two have presented mental abnormality. In two, mental symptoms preceded those of the gastrointestinal tract and skin, whereas in the third, although the skin has looked as if painted with iodine, and diarrhea has been a distressing symptom, as heretofore stated the mind has not become affected.

One's home is crowded and dirty: the others live in clean, sanitary dwellings, but all have spent their days in one of the garden spots of the earth—Oxford county, Maine.

ATYPICAL INFANTILE PARALYSIS.4

BY F. L. WACHENHEIM, M.D.

New York.

Pediatrist to Sydenham Hospital and Mount Sinai Hospital Dispensary.

One of the striking features of the present epidemic of infantile paralysis, which has prevailed since 1907, is the large proportion of atypical cases. The typical and classical form, of which a few cases were seen formerly almost every year, runs about

4Read before the Pediatric Section, New York Academy of Medicine, October 17, 1913.
the following course. The patient suddenly falls ill with moderately high fever, more or less marked gastrointestinal symptoms, and general weakness of the extremities; in a few days the fever abates, leaving the child paralyzed in one or more limbs. This paralysis gradually passes off, except for one group of muscles in usually one of the lower extremities, which remains atrophied and disabled for life.

In former days a very few cases occurred that varied from the above picture; such were the polioencephalitis of Wernicke and the poliomyleoencephalitis of Strumpell, both even then regarded as possible variations from the type described above. The acute ascending paralysis of Landry was looked on as distinct. All these cerebrospinal affections were rare and very imperfectly understood; infantile paralysis was considered a disease of the anterior horns, usually of the lower spinal cord, rarely involving other portions of the gray matter. One of my own patients, however, illustrates the exceptions. About seventeen years ago, she went through a febrile affection with the result of a severe and permanent paralysis of the deltoid, thenar, hypothenar, scapular and dorsal muscles of both sides, consequent disability of both upper extremities and a marked scoliosis. I understand that this case was not correctly diagnosed at the time, because of its exceptional features; in the light of recent experience, a similar case would hardly cause any diagnostic difficulty to-day.

During the epidemic of last fall, I observed in all seven cases, of which only one was typical. I saw this one about a month after the onset, presenting a severe paralysis of one leg, and a slight and disappearing paresis of the other. The history of the attack was the familiar one of transient fever and rapidly developing weakness of the extremities, followed by partial remission of the latter symptom. This case therefore presented nothing unusual, whereas all the others were so atypical as to be worth recording in some detail.

Case I. This child was seen by me in consultation with Doctor Koronesky. The child had been sick for several days, with temperature up to 106° F.; the flaccid posture of the left arm at once indicated paralysis of the left deltoid muscle, otherwise there was a general muscular weakness, and a temperature still reaching 105° F. Ordinarily, in a case of such severity, the prognosis would seem doubtful as to life, and poor as to restitution of the chiefly affected muscle; nevertheless, the child made a rapid and complete recovery, save for, strangely enough, a slight weakness in the left leg, but an entire restoration of the deltoid.

We have learned that complete restitution is not so very rare, but we look for this favorable outcome rather in the mild and abortive cases, hardly those of the very severe type, with high fever. Temperatures of 106° F. are uncommon in infantile paralysis, though some authors, for example, Stephens1, mention them. I do not feel certain that they are prognostically especially unfavorable in poliomyelitis, any more than in other diseases of early childhood. A fatal outcome in this disease is likely to result from other causes rather than the fever alone, though we must bear in mind that in infantile paralysis a high temperature may be a bulbar symptom by itself, and therefore of bad omen.

Case II was seen by me in consultation with Doctor Bingham. There had been a slight fever, with gastrointestinal symptoms, for several days, but the temperature had fallen to normal. During the last few hours there had been noticed a growing stupor, with weakness of all the extremities; when I saw the child it was practically comatose, so that a cerebral disturbance was evident. The reflexes were almost absent in the lower extremities, but otherwise nothing precise could be elicited, as the child's mental condition precluded any voluntary movements. In view of the prevalence of a local epidemic the diagnosis of infantile paralysis was not difficult. As the child's mental condition became normal, and one deltoid muscle showed total paralysis.

This case forms a fitting introduction to four others, all of which presented cerebral symptoms. Patients suffering from the cervical form of poliomyelitis are especially subject to at least transitory involvement of the gray matter of the medulla oblongata and basal ganglia, possibly also the convexity. The deep somnolence, often progressing to stupor and even coma, is a characteristic and alarming feature of this group. I cannot, however, point with certainty to a case of severe and permanent involvement of the cortex, as described by Clark2, and therefore do not need to enter upon a discussion of the much mooted question as to which forms of acute polioencephalitis should be regarded as mere variations of acute infantile paralysis. Many authors insist that the cerebral affections associated with poliomyelitis do not affect the cortex, but only the basal ganglia; others, including Clark himself, do not accept this restriction. The whol e matter is evidently very far from a final decision, but the frequent grave disturbances of the sen sorium, of which we have all seen striking instances, as well as the extreme restlessness and the involuntary movements of the extremities that are so often observed, not to speak of general convulsions, are all strong evidence in favor of Clark's view.

The remaining cases were all observed in the wards of Sydenham Hospital, and could therefore be studied in detail.

Case III. B. D., male, aged seventeen months, admitted October 20, 1912. Previous history of no significance. Present illness began on October 15th, when the parents noticed that his head fell backward, and that his face was flushed; later in the evening it was found that both arms hung limp. Patient vomited once that night; no convulsions, but the eyes were staring and turned upward. On admission the child was practically comatose, with eyes open, tossing about, moving its legs freely, as well as the forearms, but not the neck and shoulders. The pupils reacted to light; there was no strabismus noted; but a slight facial paresis appeared to be present. The muscles of the shoulder girdle and neck were completely paralyzed; the other muscle groups were slightly, if at all, affected, but the knee jerks were preserved.

In the course of a few days the stupor cleared up gradually; as the child began to smile, there was noted a slight facial paresis, which soon disappeared. The temperature did not at any time rise above 100.3° F. The paralyzed muscles showed no change for some time. On October 23rd there appeared an intense sweating, in large drops, limited to the face, with a normal body temperature; this phenomenon persisted for a number of days in a diminishing degree; general perspiration was not conspicuous at any time. Early in November there appeared a slight improvement in the deltoid muscles; at that time the electrical tests showed reaction to faradism in the shoulder group and the sternomastoïd, reaction of de-

---

1Intercolonial Medical Journal of Australasia, November 20, 1908.
2American Journal of the Medical Sciences, April, 1912.
generation in both trapezi. This picture remained with- out change until the patient’s discharge on November 14th. The blood count showed 17,000 leucocytes; slight diarrhea, gradually falling to normal; polynuclears seventy-four per cent., falling to sixty-three per cent.; Von Pirquet reaction negative.

This case is clearly one involving the uppermost portion of the cervical cord, with special implication of the origins of the spinal portion of the spinal accessory nerve, in itself a rare type. It presents, moreover, some remarkable features in addition. I can find no similar instance of localized facial sweating in the literature, though it is true that many authors, such as Krause and Müller-mention general profuse perspiration as rather characteristic of poliomyelitis. Curiously enough, Higieri notes anhidrosis in this disease. General hyperhidrosis in infantile paralysis may very well be attributed to disturbance of the sweating centre in the medulla oblongata, and is therefore essentially likely to occur in cases of the cervical and cerebral types. In the present case this theory fails, although involvement of the medulla oblongata could not be excluded and was, in fact, probably present to a higher degree; it is more reasonable to bring this local sweating into relation with the slight facial paresis, which was present in the early stages of the disease, though, even under this hypothesis, the connection is not as clear as we could wish.

I must not fail to mention that a well-known colleague, who saw the patient prior to admission, gave a doubtful prognosis as to life, evidently fearing an ascending paralysis, with dangerous bulbar symptoms. I suspect that the medulla oblongata was actually slightly involved, as the higher cervical centres undoubtedly were, though alarming symptoms did not develop. It is notorious that fatalities are not very rare in cases of this type. As to evidences of brain implication, the involvement of the sensorium was unusually marked in this case, for a day or two amounting to true coma vigil. The eyes remained open, all the more readily because of the slight facial paresis present.

I may add that this case was finally referred to an orthopedic institution to secure some support to the head, before its final return home. In view of the electrical tests, it is extremely doubtful if the trapezi will recover sufficiently to enable them to support the head unaided. The child is therefore, in all probability, doomed to a decidedly uncomfortable future, unless it can obtain relief from one of the neurological operations now rapidly gaining in vogue. In this case the difficulties will be decidedly greater than in those cases affecting the extremities, where, for example, in the distribution area of the brachial plexus, considerable success is said to have been attained.

Case IV. B. S., male, aged thirteen months, admitted October 16th. No previous illness. Present illness began on October 11th, when the mother noticed that the child was feverish and had its mouth drawn to one side; next day the baby was weak in all its extremities, and seemed to suffer pain; on the 13th there was vomiting, increase of fever, and paralysis of the legs. On admission the child was rolling its head from side to side, the right side of the face was flushed and flattened out, there was a paresis of all the extremities. The pupils were uneven, and reacted to light feebly, the mental condition was slightly altered, and the child seemed unable to close right eye. Up to October 29th there was a slight fever (maximum 106° F.), the extremities gradually returned to normal, though the del- toids remained paralyzed. The right optic nerve and lagophthalmos resulted in a purulent conjunctivitis that required special treatment; as the child’s mentality cleared up, the paralysis of the right facial nerve became the conspicuous feature of the case. The blood count on admis- sion was 17,000 leucocytes, with one hundred and thirty lymphocytes; three weeks later we found 8,000 leucocytes, with thirty-three per cent. of lymphocytes; the urine was normal; von Pirquet reaction negative. Tests with farad- ism on October 25th showed reaction of degeneration in all branches of the facial nerve on the right side, none in other muscular group. There was profuse general perspira- tion on one or two days when the temperature exceeded 100° F. The condition of the facial nerve remained stationary up to the day of discharge, November 9th.

This case was a typical one of poliomyelitis, with the main lesion in the pons. It presented no features calling for special comment, except the site of the inflammatory process, which we have now learned no longer to regard as a great rarity, though it was formerly so considered.

Case V. V. C., female, aged two years, admitted Octo- ber 28th, 1912. Child had been sick two weeks; onset with fever, no vomiting, restlessness, convulsions and headache. Two and a half days after the onset the child was unable to use the right side, though at that time the left side was normal. The parents were unable to give a history of any affection of this type in the family. Physical examination showed bilateral truncothoracic meningitis. There was no aspiration of the eye, and no paralysis of the facial nerve. The question of poliomyelitis was raised.

On examination the child was found to have all four extremities paralyzed, with a marked flaccid paralysis of the left side of the face, as well as partial paralysis of the left side of the tongue. The pulse was 130 per minute, but the temperature 101° F. The blood count on admission was 18,000 leucocytes, with 70 per cent. of nul- leucocytes; the urine was normal. There was profuse general perspiration; the temperature rose to 104° F., and was accompanied by vomiting, diarrhea, and flushing of face. The condition of the facial nerve remained stationary up to the day of discharge, November 9th. It should be noted that on November 23rd the temperature fell to 100° F., and remained normal for the remainder of the fever.

In September, 1912, the child was readmitted with symptoms of bronchopneumonia and marked cardiac weakness, and it succumbed rather suddenly to an attack of acute dilatation of the heart a few days later. Autopsy not obtained.

In this case it is obviously impossible to determine the relation of the cardiac symptoms to the cerebrospinal affection. Prolonged subfebrile tempera- tures with tachycardia are not uncommon in poliomyelitis, but observation of seven weeks is unusual and should, as in this case, lead to a careful search for some other cause. The occurrence of asystole might have been due either to the polio- myelitis or to the cardiac weakness, but the relative share of these two affections seems to me indeter- minable. There is no doubt, however, that in this case the involvement of the gray matter was un-
usually extensive, as shown by the implication of all extremities and the pupillary and mental phenomena; it is therefore not impossible that this patient suffered from grave impairment of the cardiac innervation, which led to a fatal outcome as soon as a special strain was put on the heart by the attack of bronchopneumonia. It is well known that a fatal paralysis of the diaphragm, caused by a lesion in the centre supplying the phrenic nerve, is not excessively rare in poliomyelitis. It is among the possibilities that the present case may be assignable to this group.

Case VI. A. J., male; aged nine months; admitted October 17th, 1912. For a week past he had suffered from fever, vomiting, gradually presenting rigidity of the neck, later general muscular rigidity; said to have lost in weight. On admission patient lay in extreme gun hammer attitude, with tonic spasm of all muscles; fontanelle not bagged; markedly; pupils equal, pulse 114, temperature 102° F., marked Kernig phenomenon; increase of patellar reflexes; weight 6,780 grammes. A lumbar puncture yielded eight c. c. of a turbid fluid under moderate pressure; the sediment was composed of lymphocytes, with few polymorphonuclear clear cells and no meningococci. The von Pirquet reaction was negative, the blood cell count showed 25,000 leucocytes, twenty-nine per cent. lymphocytes. An examination of the ears by Doctor Jarecky showed some retraction of the drum membranes, but no evidence of acute otitis or perforation. The following day the temperature did not go above 101° F., and in a few days more was normal, but the general condition remained unchanged; the weight of child, very curiously, remained quite stationary between 6,700 and 6,800 grammes. On October 23d, a clear cerebrospinal fluid was obtained, which developed a fibrin clot on standing, did not reduce Fehling’s solution, and proved to be sterile when cultivated. At this time it was noticed that the fontanelle was becoming depressed. A few days later the spastic condition began to improve rapidly, to disappear by the beginning of November; the infant began to crawl about, but acted stupidly and seemed to be amaurotic; its hearing appeared normal. After November 12th a rapid gain in weight set in, and the disease had evidently run its course, leaving a residuum of mental impairment and blindness, without peripheral palsies of any kind. The patient was discharged on November 26th.

Early in November I had an examination of the eyes by Doctor Jarecky showed a very intense papillitis, much of which was still present at the end of the month; the pupils did not react to light. The treatment consisted essentially in the administration of hexamethylenamine, with general measures as indicated. At the beginning antimeningococcus serum was injected, until the bacteriological findings and the character of the cerebrospinal fluid excluded the diagnosis of epidemic meningitis.

The inclusion of this case, apparently one of meningitis, in the group under discussion, rests on the following points of differential diagnosis. Cerebrospinal meningitis is excluded because of the preponderance of lymphocytes in the cerebrospinal fluid, the absence of meningococci, the rapid recovery from the uncommonly severe posterior basic symptoms, and the absence of an epidemic at the time. Tuberculous meningitis is excluded by the high leucocyte count, the acute onset, the favorable outcome, and the negative von Pirquet reaction.

The other forms of meningitis, such as are caused by streptococci, pneumococci, or influenza bacilli, would show the respective germs, and also end fatally; we are therefore safe in excluding them also.

On the other hand, it is shown by all the extant post mortem records, that poliomyelitis is always accompanied by a more or less severe meningitis. While this is usually of a mild type, it may be sufficiently intense to cause characteristic symptoms for a number of days or weeks, and even occasionally be responsible for a fatal termination. I particularly wish to call attention to the series of cases reported by Koplik, in which symptoms recalling both cerebrospinal and tuberculous meningitis dominated the clinical picture throughout the course of the disease, the most striking features being severe spastic manifestations, such as opisthotonos and Kernig’s symptom. While I cannot find records of another case presenting optic neuritis terminating in atrophy and amaurosis, such an un-
to attract the notice of the attending physician, and clear up speedily all remaining doubts as to the type of disease. It is hardly necessary to add, as a final corollary, that the prognosis as to life is fairly good; still, unfortunate after effects, such as paralysis of some muscular group, mental impairment, and amaurosis, may remain, so that it is well for us not to be too optimistic in our predictions. I may add the interesting circumstance that resulting paralyses are apt to be of the flaccid type distinctive of poliomyelitis, not spastic as after ordinary meningitis.

The remarkable variations displayed by so small a clinical material are sufficient to convince us that infantile paralysis, once regarded as a peculiarly localized disease, is one of the most protean affections of the central nervous system.

THE CANCER MORTALITY OF GREATER NEW YORK.*

By Frederick L. Hoffman, Newark, N. J.

The probable number of deaths from cancer in the United States during 1913 will be about 75,000. Of this number, approximately 30,000 will be deaths from cancer of the stomach and liver; 12,000 from cancer of the uterus and other female organs of generation; 10,000 from cancer of the peritoneum, intestines, and rectum; 7,000 from cancer of the breast; and the remainder, cancer of other organs and parts. In the State of New York, during the year 1912, there were 8,234 deaths from cancer, equivalent to a rate of eighty-six per 100,000 of population, which is above the average for the United States at large. The number of cancer deaths in greater New York, in 1912, was 4,071, and the corresponding cancer death rate of 80.9 per 100,000 of population was the highest on record for the city since the records have been kept. The average cancer death rate of greater New York for the last five years has been seventy-seven per 100,000 of population, which compares with ninety-four for London, 109 for Paris, and 107 for Berlin. The corresponding rate for Chicago was seventy-eight; for Philadelphia, eighty-six; and for Boston, 107. In 1912, the cancer death rate of greater New York was sixty-six for males, and ninety-six per 100,000 of population for females. The excess in the mortality of females is almost entirely due to cancer of the uterus and cancer of the breast.

The cancer death rate of greater New York has increased during the last twenty years from fifty-nine to eighty-one per 100,000 of population. The male cancer death rate of greater New York has increased forty-three per cent, and the female rate during the same period has increased thirty-three per cent. In the old city of New York, or the boroughs of Manhattan and the Bronx, the cancer death rate during the last fifty years has increased from twenty-four to eighty-six per 100,000 of population, or at the rate of 253 per cent. during the intervening period. Cancer has increased in greater New York at all ages, but the increase has been most marked at the ages of fifty-five years and over. The rate at this period of life has increased thirty-one per cent. during the last five years, when compared with the average rate during the previous five years. The rate has increased in all of the boroughs, but not to the same degree, partly on account of the influence of the hospital mortality, since the deaths in institutions are not redistributed according to the residence of the deceased. There has been an increase in the mortality from cancer of all organs and parts, except cancer of the skin, which shows a slight decrease, for the last five years compared with the previous five years.

As far as it is possible to judge, the Jewish and Italian populations are subject to at least average cancer death rates. There are no very trustworthy recent statistics for greater New York, but the available data for Hungary and the city of Vienna sustain the conclusion that cancer among the Jewish population is of a relatively high degree of frequency. Since a rather large proportion of the Jews in greater New York are of recent foreign origin, and as such a somewhat select class and mostly of the age period at which cancer is not common, it is readily apparent why, in medical and surgical practice, cancer cases among Jews in greater New York should not be as frequent as might otherwise be the case. According to the statistics of the board of health for the last two years, the proportionate mortality from cancer among persons of Russian and Italian parentage has been relatively high, so that the foregoing conclusion is sustained by the only available data at the present time.

The observed increase in the incidence of cancer in greater New York would unquestionably have been much larger were it not for the gratifying results of early operative treatment. Unfortunately a large proportion of the patients admitted to cancer and other hospitals are in too advanced a stage of the disease to warrant a hopeful prognosis. Early operative treatment alone can apparently secure reasonably satisfactory results, and in any event prolong life for a number of years. Of 1,337 patients admitted to the General Memorial Hospital and treated on account of malignant disease during the period ending with 1911, only 105, or 7.9 per cent., died. The proportion discharged as cured was thirty-four per cent.; as improved, twenty-nine per cent.; while the remainder were either not improved or still under treatment at the end of the year. Of 262 women patients treated for cancer of the generative organs, thirty-six per cent. were discharged as cured; thirty-four per cent. as improved; and not quite ten per cent. died. Of 285 patients treated for cancer of the breast, only five, or 1.8 per cent., died. Unquestionably even better results could be secured by the earliest possible operative treatment. Unfortunately a large number of cancer patients delude themselves with unwarranted hopes of a spontaneous cure, or a cure by other than surgical methods, which, while occasionally successful, are, as a rule, delayed and often a disastrous disappointment.

*Abstract of address delivered at the meeting of the Eastern Medical Society, New York, October 17, 1913.
Price Essays.

Questions for discussion in this department are announced at frequent intervals. So far as they have been decided upon, the further questions are as follows:

CXL.I.—How do you treat frostbite? (Closed.)

CXL.II.—How do you treat chronic constipation? (Answers due not later than January 15, 1914.)

CXL.III.—How do you treat gallstone colic? (Answers due not later than February 16, 1914.)

Whoever answers one of these questions in the manner most satisfactory to the editor and his advisers will receive a prize of $25. No importance whatever will be attached to literary style, but the award will be based solely on the value of the substance of the answer. It is requested (but not required) that the answers be short, if practicable no one answer to contain more than sixty words; and our friends are urged to write on one side of the paper only.

All persons will be entitled to compete for the prize whether subscribers or not. This prize will not be awarded to any one person more than once within one year. Every answer must be accompanied by the writer’s full name and address, both of which we must be at liberty to publish. All papers contributed become the property of the Journal. Our readers are asked to suggest topics for discussion.

The Prize of $25 for the best essay submitted in answer to Question CXXXIX was awarded to Dr. J. Walker Moore, of Philadelphia, Pa., whose article appeared on page 1117.

PRIZE QUESTION NO. CXXXIX.

TREATMENT OF CHANCROIDS.

(Continued from page 1172.)

Dr. E. IV. Phillips, of Chattanooga, Tenn., says:

In the absence of complications the following routine is effective: Cleanse the glans and prepuce with soap and water; apply hydrogen dioxide to the ulcer, remove secretions and dead tissue and dry with a piece of gauze, thus obtaining a surface capable of absorbing the anesthetic. Dust this surface well with powdered cocaine, or apply to it a bit of absorbent cotton saturated with a four per cent. solution of cocaine. Wait five minutes, test the anesthesia, and, if good, again dry the sore and cauterize it thoroughlv with concentrated nitric acid. Apply the acid on a small swab, destroying all the softened tissue that forms the floor and undermined edges of the chancroid. If the foregoing procedure has been carried out, the acid causes no pain. In dressing, use a "penis roll" thirty inches long, conveniently made by twice folding lengthwise a strip of three inch gauze bandage. Apply this roll, comfortably tight so as to fill the sulcus, separate the glans from the prepuce, and completely cover in the sore. Moisten this dressing and keep it moist with black wash or a four per cent. boric acid solution. Dress daily, or oftener if the dressing becomes displaced. When the slough separates, if the cauterization has been complete, there is left a clean ulcer which rapidly heals under daily dry dressing. Old or phagedenic chancroids may require recatherization on the third day.

If there exists an inflammatory phimosis, concealing the chancroid from direct attack, it can sometimes be overcome by soaking the penis for half an hour twice daily in a warm, one in 4,000 permanganate solution, introducing a drain within the prepuce, and applying a wet dressing. Should this fail to render the chancroid accessible within thirty-six hours, it is necessary to make a dorsal slit under cocaine, and treat the sores as above, bandaging back the preputial flaps. Usually in these cases multiple chancroids with an active balanoposthitis are found.

This technic gives much quicker cures and fewer buboes than any other with which I am acquainted. Even if considerable inguinal adenitis exists it commonly subsides when the chancroid is properly cauterized and dressed. Rest in bed, and cold applications to the affected glands, are indicated in cases of this sort. A well developed bubo obviously requires appropriate surgical treatment; injection of iodoform, drainage, or enucleation of the glands. Genuine chancroidal infection of a lymph node, fortunately not common, requires nitric acid cauterization, free drainage, and frequent dressing.

It is necessary to follow up only a moderate number of chancroid cases—an observation easily made in the naval service—to learn that the most typical of chancroids may precede a beautiful syphilitic eruption. Each patient discharged from treatment for chancroid should be warned of this, and instructed to return for observation at the end of a month. The clinical points that lead one early to suspect mixed infection are: An incubation period of ten days or more; induration about the base of an ulcer not irritated by previous treatment; and, especially, the persistence after cauterization of a sluggish sore, perhaps with some peripheral infiltration, that slowly extends and will not heal. In such cases a Wassermann test should be made after the chancroid has existed for two weeks, and if negative, repeated in ten days. If syphilis is found, vigorous constitutional treatment should be instituted at once. Every surgeon knows that nitric acid is effective in the cure of chancroid, but, possibly because of its apparent harshness, few use this agent except in refractory cases. The routine employment of nitric acid was brought to my attention by
Surgeon H. M. Tolfree, U. S. Navy, who has for some time obtained excellent results with it.

Dr. John Ballagi, of Homestead, Pa., says:

In case the diagnosis is correct and the ulcer is really a chancreoid, wash and cleanse the whole penis or vagina, not forgetting the numerous folds and nooks of the female genitalia. (Women with chancreoids are very seldom met with in general practice). Use soap and water, after that a two per cent. solution of carbolic acid or a one tenth per cent. of bichloride. Then cauterize the ulcer thoroughly. The stick of silver nitrate is not good, unless with a very fine point. I prefer pure nitric acid or concentrated liquid carbolic acid, but the adjacent parts must be protected by petrolatum. If one can see the patient in short intervals, an excellent, painless caustic is the saturated solution of camphor in liquid carbolic acid. Put a small bit of cotton soaked in this solution on the ulcer; cover it with several layers of plain gauze and leaving this on for five or six hours; then remove it, dust the sore with boric acid, and repeat the procedure on one or two consecutive days.

With men special care must be taken to provide against paraphimosis. If the prepuce is roomy and can be pushed back easily, the best is to keep it behind the glans constantly with bandages. But when tight and there is danger of paraphimosis do not try to keep it retracted. Better, put gauze around the whole glans and pull the prepuce forward over it. When there is a phimosis already and the edge of the prepuce is full of ulcers and fissures, do not make an incision, much less a circumcision. Syringe out the preputial sac with warm one per cent. carbolic acid solution or a one in 2,000 bichloride solution, then push so many strips of iodoform gauze between glans and prepuce as will go in. Smear the strips well with borated petrolatum. Dressings must be changed twice or at least once every twenty-four hours, and insist on doing it yourself.

Ulcers around the meatus are hard to manage. The dressing has to be fastened on with two crosswise strips of adhesive plaster, and the patient instructed not to urinate more than two or three times a day, removing the dressing before and replacing it after each urination.

As a rule, cauterization, except with the camphor-carbolic as stated above, does not need to be repeated. Instead, a mild, slightly irritating antiseptic is to be employed, provided the ulcers are accessible. There is a whole army of drugs used, but two of them only can be regarded as almost specifics, iodoform and the copper salts.

The first is the sovereign remedy for chancreoids, particularly when the base of the ulcer is covered with a dirty, membranelike debris. Substitute for iodoform are not “just as good.” Iodoform must be dusted on but sparingly and the crystallized form is to be preferred. To be sure, its odor is far from being pleasant, but when one takes care not to spill any on the patient’s clothes and covers the ulcer carefully, the odor cannot be detected except in close proximity. Deodorized iodoform does not exist. When for any reason iodoform cannot be employed (the patient objects to it sometimes), one may try pyrol tetramido, or pure boric acid, or bismuth subnitrate, etc. Sluggish ulcers, the creeping, serpiginous form, may require some stronger stimulant like calomel or salicylic acid, besides repeating the cauterization every three or four days.

Phagedenic (dangerous) ulcers need a very thorough washing with bichloride, or better, with permanganate solution two or three times a day, and dressing with a one per cent. chlorinated water. Continuous wet bichloride dressings, or surgical interference may become necessary in—fortunately rare—desperate cases. Internal treatment is indicated: Arsenic, iron or other tonics. To lymphatic persons iodine, iron iodide or arsenic must be given.

When the ulcer begins to granulate and shows a clean, suppurring surface, use copper sulphate or acetate. Put bits of cotton or gauze saturated with a one per cent. solution of the salt on the ulcer and leave it there from twenty-four to forty-eight hours.

An unpleasant sequela of chancreoids frequently met with is the bubo (commonly called “blue-ball”). It is not always possible to prevent it; it may develop in spite of the most careful treatment. Patients must avoid much walking, traveling, athletics, dancing, horseback riding, and sexual excitement; alcohol is absolutely prohibited. Prescribe rest, plain food, and salines. Should the glands begin to show tenderness or enlargement, put the patient to bed, shave the skin, and order compresses with plain warm water to put on the affected gland; then sometimes the inflammation will subside. If not, let the patient get up (if he can) and walk around; that will hasten the coalescing of the separate individual glands and one will not have to repeat the incision for each gland. When there is fluctuation, but the skin is healthy looking yet (red, but not “blue”), aspiration may be tried. Aspirate the pus with a thin trocar and, without removing the needle, inject into the cavity about the same quantity of ten per cent. iodoform emulsion in glycerin.

In opening a bubo I have found it best to make an ample longitudinal incision, pressing out the pus, but to do no syringing except with warm salt solution, and to pack with iodoform gauze. Sutures are superfluous.

There are several “don’ts” in treating chancreoids: Do not use any ointments on the ulcers. Do not cut, except a paraphimotic ring, a suppurated gland, or the frenulum, when perforated by an ulcer. Do not paint the skin over the bubo with tincture of iodine. Do not put on it ointments or cataplasms.

Contrary to authoritative statements (Keyes, Surgical Diseases of the Genito-urinary Organs, 1904, page 660), virulent or suppurring bubos are not and do not invariably become an open chancreoid ulcer. Do not dress the ulcer first, when ulcer and opened bubo coexist, else the bubo may become a chancreoid ulcer.

Dr. Hartwell R. Burwell, of Washington, D. C., states:

No hard and fast routine or arbitrary rule should be followed in treating chancreoids, but treatments should be governed by the underlying surgical
principles and the various indications met accordingly. Chancreoids of the milder types have been known to terminate in resolution and healing under the treatment of mere cleanliness. This is an important feature of successful treatment. Frequent use of warm saline or bichloride solutions one to 5,000 or one to 10,000 is valuable to prevent the spread of the disease, removing the irritant, contagious, and infectious discharges and secretions from the ulcer as well as the products of mixed infection. Most chancreoids are sluggish and indolent and if more stringent measures in the form of cautery or the occasional application of lunar caustic or phenol eighty-six per cent, followed by alcohol. Deep phagedenic ulcers are benefited by a destructive cauterization with fuming nitric acid. By this form of treatment, a slough, consisting of the diseased tissue, is thrown off, leaving a clean ulcer base for healing. Scarlet red may be applied to the skin margin to assist epithelialization. Often the repeated use of the tincture of iodine preceded by a two per cent, to four per cent. cocaine solution, is efficacious in producing a cure in an indolent, resistant sore. Care should be taken to prevent contact with chancreoids, by proper arrangement of dressings containing medicaments, as absorbent cotton soaked in mild bichloride solution. Calomel and other powders are used but they often cause crusting and the retention of the secretions. The use of iodoform as a dusting powder is satisfactory in some cases. Ointment of ammoniated mercury is a good dressing for sores on exposed surfaces. Conditions requiring operative intervention are few but well marked and are due nearly always to anatomical defect, position of the ulcer or some local complication. A tight prepuce which resists retraction makes access to a concealed sore impossible. A paraphimosis or balanitis due to the irritation of a coexistent Neisser infection adds to the difficulties. These conditions must be treated before results can be obtained in the primary object of treatment. Mild alkaline washes, or solutions of boric acid, or hydrogen dioxide diluted with warm water, injected by means of small glass syringe between prepuce and glans several times a day, are useful in reducing the local inflammatory conditions mentioned. This process removes blocked secretions and conditions improve within a few days. If the foreskin now permits retraction, the chancreoid may be cared for as already mentioned, but if still tight and adherent, the best operation to perform in such cases is to make lateral incisions under local anesthesia using one per cent. or two per cent. cocaine solution. This measure exposes the preputial ulcer and also the glans, and favors the removal of decomposed exudate and the irritating discharges which have been accumulating for days or weeks. Often firm adhesions have formed between the glans and the foreskin, the former usually presenting a wormeaten appearance. Cleanliness here, as stated above, is the sheet anchor which must be held to in order to get the best results. Later, when healing is complete, a circumcision is indicated to restore the penis to its normal appearance. Complete excision of the sore has been practised in cases of small indolent ulcers but is not recommended for fear of spreading the infection. Extensive ulceration involving the urethra may later require plastic operation and should be referred to a specialist. Existing adenitis, when suppuration is present, should be dealt with by free incision and drainage. The wound should be packed with iodoform gauze and allowed to heal from the bottom.

Under general treatment brief mention may be made of the use of mercury internally in the cure if chancreoids. Old, sluggish, indolent processes, which have resisted ordinary forms of local treatment, have been known to heal under the use of some salt of mercury and should be tried in such cases. These cases, it may be said, show a negative Noguchi reaction. Body resistance should be brought up to efficiency by attention to general hygienic measures, cleanliness, food, bowels, etc.

Dr. H. A. Giltner, of Portsmouth, Va., insists:

In the line of general measures, the patient should be kept at rest as much as possible and not indulge in severe muscular exercise or become over-heated. Alcoholic liquors should be absolutely forbidden and the diet composed of plain and digestible food. The greatest precaution should be taken that friction and compression of the penis are avoided. The essentials of the local treatment are to keep the parts thoroughly clean and dry. This is not so difficult when the lesion is on the skin, but when under the prepuce it is far from easy and also more essential.

The ulcer and surrounding parts should be thoroughly scrubbed with soap and water and then irrigated with warm bichloride solution (one in 1000). After cleansing, dust with a powder composed of equal parts of boric acid, subnitrate of bismuth and calomel. There are other good dusting powders, but the former is to be preferred. When the ulcer is small and superficial and there is but little discharge, one dressing daily is sufficient, but usually two dressings a day are necessary. In a small proportion of cases this simple treatment is sufficient to effect a cure, but in the majority of cases there is more or less destruction of tissue and sluggishness of healing which requires cauterization to stimulate the process. After cleansing the chancreoid, make a thorough application of silver nitrate solution, ten to twenty per cent., using a toothpick on which is twisted a small piece of cotton, being careful that the undermined edges of the ulcer are thoroughly touched with the solution. This application should be made every other day until healing is well under way and the ragged edges of necrotic tissue have disappeared. Some cases will require a stronger solution of the silver nitrate which may be used in any strength, even up to one hundred per cent. in some instances. Carbolic acid is in very common use for the cauterization of chancreoids, but my best results have been obtained by the use of the silver nitrate.

Cases of long standing and with considerable destruction of tissue are best treated with potassium permanganate. Crystals of cocaine or a moistened soluble tablet are placed on the sore and allowed to dissolve. A local anesthetic is necessary as the application of potassium permanganate is very painful otherwise. A paste of the permanganate is made with water and applied until the sore is
black. The cocaine is thought to be beneficial aside from the anesthetic effect, probably through the temporary hyperemia which it induces.

In addition, the treatment of serpiginous and phagedenic chancroids requires the use of nutritious foods, tonics, stimulants, and careful attention to hygiene and surroundings.

Locally prolonged immersions in, or irrigations of the penis with a one in 5,000 bichloride solution, after which a dressing of gauze wet with a saturated solution of borie acid or salt solution is applied and covered with oiled silk or other impervious material.

Old, indolent lesions, in which there is infiltration and the sloughs fail to separate, should be curetted and cauterized with pure carbolic acid. When healthy granulations begin to form, balsam of Peru makes a very satisfactory dressing.

Chancroidal phimosis requires incision of the prepuce and the best results are obtained by making lateral incisions one on each side back to the corona sulcus. All dead tissue should be removed with the curette, the subsequent treatment being the same as in uncomplicated chancroid.

Chancroidal paraphimosis is treated with hot bichloride irrigations and immersions several times a day and if strangulation occurs, an incision must be made through the constricting band.

Buboes should be painted with tincture of iodine daily and a spica applied. It is the experience of the writer that suppuration very seldom follows this treatment.

If suppuration occurs, the pus should be drawn off with an aspirator, repeating as often as necessary. If this fails incise, curette, cauterize with pure carbolic acid and pack with gauze. When the glands remain enlarged with no breaking down, or persist after suppuration, they must be excised.

(To be concluded.)

Therapeutic Notes.

Treatment of Hematemesis.—O. Grünbaum, in the Practitioner for August, 1913, states that one of the first measures in hematemesis should be to assure the alarmed patient that the condition is common and recovery the rule. Mental agitation can be further diminished by an injection of one third grain (0.02 gram) of morphia (one eighth or one sixth grain is often worse than useless, exciting the patient instead of soothing him). The author doubts whether ill effects result from carelessly transferring the patient to a bed. The head should be low if the loss of blood is so great as to lead to algnesia of the brain and consequent faintness, but in the absence of this the patient should be arranged in the position he finds most comfortable.

As for drug treatment, suprarenal extract in one dram (4 c. c.) doses of the one in 1,000 solution is advised by the author. To avoid the secondary vasodilator effect, the drug must be given at short intervals—not over an hour. Ferric chloride and tannic acid are unsatisfactory, for they convert the blood in the stomach into a hard mass, which irritates the mucosa and leads to vomiting or retching. Ergot is unsuitable because it is absorbed and leads to a rise of blood pressure. Turpentine is of great use when adrenal extract is not available; but if given frequently, even in small doses, this agent may lead to nephritis. If the adrenal extract, together with one grain (0.06 gram) of neutral calcium chloride, does not arrest the hemorrhage, lowering the blood pressure with aconite may be considered. The patient should be informed that this drug will make him feel very faint and ill, but that it cannot be helped, and that in a few days' time great improvement will occur. Two minims (0.12 c. c.) of tincture of aconite may be given every half hour until the heart rate falls below sixty or the pressure below ninety mm. Hg., or the heart becomes very irregular. If the stomach is full of blood, rendering administration of the drug by mouth futile, a dilute solution of aconite in slightly alkalized normal saline solution may be given hypodermically; or, occasionally, tincture of aconite may be added to enemata.

For the first three or four days the stomach should be kept empty and water supplied to the patient in the form of saline rectal enemata, six ounces (150 c. c.) every four hours. Only if the patient is very emaciated are nutrient enemata advisable.

When the hemorrhage has stopped, treatment should be directed to healing the ulcer. The diet should be liquid, and rich in proteid, in order to fix hydrochloric acid in the stomach. It should not contain albumoses and meat extracts. Feeding should be at relatively short intervals, and it may be advisable to neutralize the acid secretion by giving moderate amounts of bismuth subcarbonate, magnesium oxide, sodium bicarbonate, and calcium carbonate. The food should not be that especially liked by the patient, as this would lead to a more pronounced secretion of acid. Probably the best diet in most instances consists of an egg beaten up in one half pint (250 c. c.) of milk, taken every two hours.

If constipation results, liquid paraffin, when it does not cause retching and nausea, appears to be the best laxative for these cases.

Iron will hasten recovery from the anemia, but only one compound of it is suitable for these patients, the nucleide (nucleinate), which passes through the stomach unchanged, does not cause constipation or indigestion, and is readily absorbed in the duodenum. Ten grains (0.06 gram) of freshly dissolved iron nucleide may be given three times a day, its objectionable taste being largely covered with chloroform water or fluidextract of licorice.

Treatment of Seborrhea of the Scalp.—Saouraud, in Journal de médecine de Paris for April 5, 1913, is credited with the following combination, to be diligently rubbed over the scalp every evening:

R Resorcinol, r
Iethyol, r
Hydragyri oxidii flavi, r
Sulphuris precipitati, gr. viis-xv
Pyrogallolis, gr. viis-xv 0.5-1 gram
Olei cadini, r
Adipsi liquore, r
Petrolati,
M. Frat unguentum.

Each morning the scalp should be washed with soap and water.

NEW YORK, SATURDAY, DECEMBER 20, 1913.

RADII IN THE TREATMENT OF CANCER.

Had it not been that the speakers were men of
the type of Howard A. Kelly, of Baltimore, and
Robert Abbe, of New York, at a meeting held last
Monday night at the College of Physicians of
Philadelphia, the positiveness with which they
urged that radium could cure cancer when the
neoplasm was so situated as to make it possible to
place the radioactive substance into contact with
it, would have inspired skepticism. Fortunately,
there is no ground for any such spirit; the results
obtained are in keeping with the observations of
several others, Louis Wickham, of Paris, for in-
stance, who has long preached that properly used,
radium could master, not only cutaneous epi-
theliomata, but also grave cases of cancer situated
in other accessible regions. Sarcoma in its various
forms he found to yield to radiation even more
quickly than epithelioma, while lymphadenomata
and growths due to Mycosis fungoides proved also
very susceptible to its effects.

In keeping also with Wickham's advice, how-
ever, the speakers advocated surgical removal
whenever possible, the limited amount of radium
available at the present time rendering a prolonged
wait to receive its benefits dangerous in the ex-
treme—owing doubtless to the sudden exacerbation
of growth and other complications which would
thus be given time to develop. Fortunately, the
dearth of radium will in time be remedied; the
pitchblende mines and the carnotite fields to
which we referred editorially in our issues for
October 18 and November 8, 1913, not only afford
a vast source of radioactive earths, but through the
generosity of Mr. Coleman Dupont, Dr. Howard
A. Kelly, and Dr. James Douglass, a prominent
engineer of New York, all the radium derived from
them will be used for philanthropic purposes.

Radium therapy has, like other valuable method-
rn, received its share of criticism owing to the wide
field over which its virtues seem to be steadily ex-
tending. It is becoming increasingly evident, how-
ever, that successful results can be expected only
when the operator is possessed of sufficient radium
to obtain good results, and provided he has the con-
siderable experience required to use it judiciously.

ACCURACY OF THE CLINICAL
THERMOMETER.

One seldom hears a physician express any doubt
as to the accuracy of his thermometer, which is, in
fact, almost the only instrument of precision which
is in well nigh universal use among the profession.

Possibly an explanation for this confidence lies
in the fact that, whatever the price, the instrument
is always accompanied with a certificate of accuracy.
We have often been impressed by the fact that none
of these certificates ever shows any variation of the
tested instrument from the standard of absolute
accuracy against which it is supposed to have been
tested. In spite of this certificated accuracy of
clinical thermometers, many physicians must have
noticed that simultaneous observations on a single
patient, made with two instruments, seldom give
identical results. It has recently been pointed out
by a correspondent in the Lancet (October 4, 1913,
p. 1029) that low priced thermometers are far from
accurate; he tested several batches of thermome-
ters selling at from two dollars and a half to four
dollars and quarter a dozen.

With three dozen of the cheaper of these instru-
ments immersed simultaneously in a bath of warm
water, the readings varied from 98.2° to 101.6°F.;
a second similar batch in another bath varied be-
 tween 98° and 105.4°F., these being the higher
priced instruments; a third group of eighteen in-
struments of the same price (four dollars and a
quarter a dozen) immersed in a bath at 98.4°F. as
recorded by a Kew certified thermometer, varied
between 95.4° and 97.2°F., not a single instru-
ment rising to the actual temperature; these same instru-
ments immersed simultaneously in a bath of warm
water, the readings varied from 98.2° to 101.6°F.;
a second similar batch in another bath varied be-
 tween 98° and 105.4°F., these being the higher
priced instruments; a third group of eighteen instru-
ments of the same price (four dollars and a
quarter a dozen) immersed in a bath at 98.4°F. as
recorded by a Kew certified thermometer, varied
between 95.4° and 97.2°F., not a single instru-
ments immersed simultaneously in a bath of warm
water, the readings varied from 98.2° to 101.6°F.;
a second similar batch in another bath varied be-
 tween 98° and 105.4°F., these being the higher
priced instruments; a third group of eighteen instru-
ments of the same price (four dollars and a
quarter a dozen) immersed in a bath at 98.4°F. as
recorded by a Kew certified thermometer, varied
between 95.4° and 97.2°F., not a single instru-
EDITORIAL ARTICLES.

ments subjected to a temperature of 105.2°F. read from 101° to 103.6°F.

These findings prompted the Lancet (November 8, 1913, p. 1342) to undertake observations with instruments varying in price from thirty-six cents to sixty cents each, all stated to be half minute thermometers. In this series of tests the individual variations were far smaller than in the previous group, but it is to be remarked that not over a dozen instruments were used for the entire series of observations. After immersion for half a minute, at temperatures from 95.3° to 105.3°F., only seventeen out of forty-seven readings were within four tenths of a degree Fahrenheit of the actual temperature of the water. After immersion for two minutes, twenty-eight out of forty-seven readings were correct within two tenths of a degree. In the first group of readings the maximum variation recorded was one degree below the correct reading; in the two minute tests the maximum was six tenths of a degree below the actual temperature. Very few of the instruments in this series of tests read much above the actual temperature of the bath in which they were immersed.

From these findings it is obvious that the clinical thermometer of low or moderate price is not a trustworthy instrument—certainly is not one of precision. Just how the more costly thermometers would be found to tally with laboratory instruments of known accuracy cannot be predicted, but it is reasonable to suppose that a certified instrument for which two or three dollars is charged would be found to be fairly accurate. The findings of the Lancet laboratory with regard to the inaccuracy of the clinical thermometer after only half a minute's immersion support the common practice of today of letting the patient hold the instrument for at least two minutes.

While it may seem to some that variations of four tenths or six tenths of a degree are but a small matter, it must be borne in mind that just such a variation in an instrument might well cast doubt on the diagnosis in a case of incipient tuberculosis, in which accurate temperature observations are of prime importance, both for diagnosis and prognosis.

to say that a child needs proper glasses; it is another to see that he gets them.

Thousands of children are directed each winter to have their eyes examined. Some of these consult specialists in their offices and receive adequate treatment. Others consult opticians or optometrists, who, for the sake of selling a pair of glasses, undertake to solve the intricate problems involved with a deftness and cleverness which would be remarkable if successful. The majority, perhaps, arrive almost simultaneously at the eye clinics, which are overwhelmed by this sudden and temporary increase of the most difficult and time consuming part of their work. A certain number of these children, but a comparatively small one, are set aside for the purpose of teaching, and these receive proper attention, but in our large clinics the time of the expert is fully occupied by attending to the diseases and operative conditions of the eye that present themselves. The great majority of these refraction cases have to be intrusted to the junior assistants, who attend the clinics for other reasons than to devote their entire time to the correction of the tiresome, patience-trying errors of refraction, and seldom have the skill to cope successfully with the task, so that only a small proportion of these children receive the painstaking, accurate attention to which they are entitled. The appointment of a city ophthalmologist, who prescribes from a single examination after the eyes have been placed under atropine by a school nurse, gives no better results, if indeed as good.

The problem then that grows more and more perplexing with the increasing demand for the conservation of the eyes of school children, is how to secure a means by which they may be properly examined, and it may be well to consider the solution adopted in London, as detailed by Dr. Samuel Horton Brown in the Ophthalmic Record for October, 1913 (see this JOURNAL for December 6th, page 1135).

This plan may not be ideal; the first attempt to solve a problem of such magnitude seldom is; but it presents three salient features which, we believe, must form a part of any plan that is to prove successful; viz., employment of competent ophthalmologists with adequate facilities, reasonable payment for a reasonable amount of work, and protection against overcrowding. Nothing in this militates against the use of material for instruction; on the contrary, the junior assistants, who now often have to work out their problems unassisted, would then work under the direct, personal supervision of an expert and learn more quickly how to solve them accurately. Nothing except the prospect of some reward will keep the expert down to the grinding,

THE CARE OF THE EYES OF SCHOOL CHILDREN.

One way in which the growing interest in school hygiene is shown is the increasing demand that the eyes of the children shall be conserved by proper glasses, whenever they appear to be causing trouble. This is truly as it should be, but the decision to do the proper thing does not always include provision of the ways and means. It is one thing
laborious, and usually thankless task of refraction work; he will leave it for the easier, more interesting, and indirectly more profitable branches of his specialty. No man can do more than a certain amount of work in a day and do it well. The crowds at the clinics at certain seasons are enough to make the most skilful despair; he cannot attend to all, often not to a majority, as they should be attended to, yet if a single patient complains of lack of attention an investigation is in order, and if the expert works overtime, he soon feels that he is not gaining the approbation of the authorities; hence, the limitation of the work given him to do each day to the amount that a skilful man can accomplish successfully in the prescribed time, enables him to perform it accurately and conscientiously.

Too much hurried, slipshod work is to be seen in the refraction rooms of our metropolitan clinics. Under the circumstances we cannot see how it could be otherwise, so, if the eyes of our school children are to be conserved, it would be well for the city authorities to take cognizance of the example set them by their confreres of London, and to institute measures to secure for the children adequate expert care and attention.

SOCIAL REFORM LEGISLATION.

Legislation with the view of bettering the human race, that is to say the physical and mental attributes of our breed, is going merrily on. We are unable to furnish a complete list of those States which have some eugenic law already on the statute book, but so far as it goes the following is exact. Among those who have made sterilization of defectives of various kinds a legal procedure are the following: Indiana, Washington, California, Connecticut, Nevada, Iowa, New Jersey, New York, Wisconsin, Michigan, and Kansas. With the well-intentioned plan of preventing the spread of venereal disease through marriage, the following States have thrown certain impediments in the way of marriage license procurements: Michigan, Utah, Washington, North Dakota, Indiana, Pennsylvania, and Wisconsin. These impediments vary from simply requiring the affidavit of the candidates themselves that they are free from disease, as is the case in Washington, to the procurement of a physician’s certificate of health based upon an examination which the doctor must swear he has made according to the recognized clinical and laboratory methods, as is the case in Wisconsin. Practically all the States which have so far legislated on either of these subjects, the sterilization of the unfit or the spread of venereal disease through marriage, have passed laws which are open to the most severe criticism. The most of them bear evidence of hasty preparation and construction. Legislation has apparently outrun the findings of the eugenists themselves. In connection with this subject, it is well to remember that research is a basic function of the State. It would be wise economy to spend time and money to ascertain the exact nature of the principles which underlie the inheritance of good or bad germ plasm before attempting to correct evils by methods which anticipate the results of careful scientific investigation, and which may eventually be ascertained to rest upon entirely unsound conclusions. With her usual conservative custom, Massachusetts has recognized the fact that eugenic legislation should be undertaken with the greatest caution, if at all, and has empowered and directed her State Board of Insanity, acting jointly with the State Board of Health, to investigate the subject and report to the general court early in the coming year whether further impediments to marriage should be imposed in the Commonwealth. At the coming sessions of the various State legislatures it would be good policy to emulate the State of Massachusetts and provide for calm and deliberate investigation, rather than enter upon another winter of riotous eugenic legislation.

COCAINE RECORDS IN NEW YORK STATE.

The attorney general of the State of New York has rendered an opinion to the effect that the Walker cocaine law does not require the physician to furnish a certificate to patients to whom he administers the drug: but, where the physician hands the drug to the patient to be taken away and used later, it is necessary that he should furnish the certificate stating the amount of cocaine furnished, just as the druggist is required to do. Physicians, dentists, and veterinarians are not required to make any record of the cocaine administered to patients, but only of what is handed to the patient for later use. They are required, however, to make a record of the total amount of cocaine disposed of at least once in every six months in a special book kept for that purpose. This book must be preserved for at least five years, and be open to inspection by the legal authorities.

THE PSYCHOANALYTIC REVIEW.

A new quarterly, announced as a journal devoted to an understanding of human conduct, and entitled The Psychoanalytic Review, under the distinguished editorship of Dr. William A. White and Dr. Smith Ely Jelliffe, makes its bow with the November issue. It is a handsome printed, wide margined volume of 120 pages, containing matter of the kind indicated in the title, and should be welcomed by a large clientele of physicians in our country, whose duty it is to familiarize themselves with the latest literature and teaching in the difficult and recondite field which it covers. The review is published simultaneously at Lancaster, Pa., and New York city by the Journal of Nervous and Mental Disease Publishing Company at five dollars per annum.
Harvey Society Lectures.—The next lecture in the course will be given on the evening of January 17th by Dr. Victor C. Vaughan, of the University of Michigan, on the Etiology of Spirochetal Infections.

Aftercare of the Insane.—Funds have been allowed for the employment of a social worker at the Long Island State Hospital, Brooklyn, N. Y., for the purpose of the prevention of insanity and aftercare work among the insane in the community.

Free Lectures at Harvard Medical School.—The first of a series of nineteen public lectures on medical subjects, to be given at the Harvard Medical School on Sunday afternoons, at four o'clock, will be delivered on the afternoon of January 4th by Dr. W. B. Cannon, on Recent Studies of the Bodily Effects of Fear and Rage.

Outbreak of Diphtheria in Nassau Hospital.—The Mineola Board of Health, on December 14th, quarantined the Nassau Hospital upon discovering that several patients in a ward and twelve nurses were infected with the disease. The disease was contracted from the hospital by a patient from Glen Cove, whose illness was diagnosed as typhoid fever.

Formula Bill in the House.—On December 4th, a bill was introduced in the House of Representatives by Congressman Pingree, as House Bill No. 9832, which provides that it shall be illegal to transport from one State to another, or to export, or to sell in the District of Columbia, any package of food or medicine which does not bear a complete statement of the contents.

Exhibit of the Department of Health.—A permanent exhibit of the activities of the Department of Health of the City of New York was opened on Wednesday afternoon, December 17th, in the exhibition hall of the Department of Health Building, 149 Centre Street. Five minutes were made by some of those who have rendered distinguished services in the cause of public health. Dr. Stephen Smith was the principal speaker.

Portland, Me., Medical Club.—At the thirty-seventh annual meeting of this organization, held on the evening of December 4th, under the presidency of Dr. Harold A. Pingree, the following officers were elected: President, Dr. Walter D. Williamson; vice-presidents, Dr. Alfred Mitchell, Jr., and Dr. Frank Y. Gilbert; secretary and treasurer, Dr. Roland B. Moore. The address of the evening was delivered by Dr. Owen P. Smith.

Eradication of Malaria.—At the third National Drainage Congress, held in St. Louis, Mo., April 10th, 11th, and 12th, a section on malaria eradication was organized, with the object of stimulating the study of the distribution, prevalence, and economic importance of malaria, and of devising methods to prevent the spread of this disease to a public still subject to it. The following officers were elected: President, Dr. William H. Olcott; vice-president, Dr. John B. Skene; secretary, Dr. E. J. Griscom; treasurer, Dr. S. J. Metzger. Committees: Board of censors, Dr. H. S. Davidson, chairman, Dr. J. G. Grant, and Dr. G. M. Logan; health and legislation, Dr. W. S. Chase, chairman, Dr. F. C. Reid, and Dr. in. Weller, library, Dr. J. H. Seiler, chairman, and Dr. D. S. Bowman, delegates, Dr. M. D. Stevenson and Dr. J. N. Weller; State legislation, Dr. R. H. McKay; national legislation, Dr. W. A. Searl.

Meetings of Medical Societies in Philadelphia during the Coming Week.—Monday, December 22d, Medical Society and Branches of the County Society; Tuesday, December 23d, West Philadelphia Medical Association; Friday, December 26th, Northern Medical Association, South Branch of the County Society, and the board of directors of the Alumni Club.

Eastern Medical Society.—At the annual meeting of the Eastern Medical Society of the City of New York, held on Friday evening, December 12th, under the presidency of Dr. Joseph Barsky, following officers were elected to serve for the ensuing year: President, Dr. Joseph Bieber; first vice-president, Dr. I. Strauss; second vice-president, Dr. M. Keschner; recording secretary, Dr. Samuel J. Seidorn; corresponding secretary, Dr. Harry E. Kees; treasurer, Dr. Samuel Lever; trustee, for three years, Dr. Joseph Barsky.

National Red Cross Society.—At the ninth annual meeting of this society, held in Washington, D. C., on Wednesday, December 10th, it was announced that Mr. Jacob Schiff, of New York, had made a special additional endowment of $100,000, the income to be used for the nursing service of the Red Cross, and that Mrs. Whitelaw Reid had offered to contribute $2,500 a year to the same fund for service in China. President Arthur, major general of the Red Cross, addressed the meeting.

Personal.—Dr. William H. Jefferys, of St. Luke's Hospital, Shanghai, China, delivered an address in Phila- delphia on the evening of December 9th, in which he spoke of China's great need of medical missionaries. Dr. W. W. Keen presided at the meeting.

Dr. Charles F. Sanborn, assistant superintendent of the Cook County Hospital, Chicago, will go to Cincinnati, Ohio, in January, to assume charge of the new general hospital.

Dr. C. Ross Miller, assistant house physician at Ray Brook, N. Y., Tuberculosis Hospital, has been appointed assistant superintendent of the Ogdenhusre State Hos- pital.

Dr. L. E. Burch has been appointed acting dean of the medical department of Vanderbilt University, Nashville, Tenn.

Requirements for Admission to the Long Island Colle- giate.—Beginning with the session of 1914-1915, Long Island College Hospital, Brooklyn, will require one year of college work for admission to the freshman class. In order that students may advantageously prepare themselves for entrance to the college, the medical preparatory course devoted to the subjects of physics, chemistry, biology, both didactic and laboratory, elementary physiology, French, and German, As many of the high school students in the neighborhood of New York graduate in February, a spring and summer course will be given, beginning February 2d, and continuing thirty-two weeks. The fees for this course will be $155. and, upon its completion, the student will be granted a certificate which, with the presentation of the regents medical student certificate, will entitle the holder to admission to the freshman class of Long Island College Hospital.

Travel Study Club of American Physicians.—The physicians who made a study tour of Europe last year under the presidency of Dr. William B. De Garmo, of New York, have organized into a permanent body to be known as the Travel Study Club of American Physicians. By constitutions and bylaws have been adopted and the following officers elected: President, Dr. Louis Livingston Seaman, of New York; vice-presidents, Dr. William B. De Garmo, of New York, Dr. Edward B. Heckel, of Pitts- burgh, and Dr. H. E. Enright, of Philadelphia; secretary, Mr. Richard Kova, of New York; treasurer, Dr. F. H. Albee, of Breitzefeld, of New York; Dr. A. J. Crowell, of Charlotte; Dr. H. F. Foss, of Philadelphia; Dr. J. F. Lord, of Omaha; Dr. J. F. Perry, of Galesburg, and Dr. John Pount, of Kansas City. The Travel Study Club plans for a tour in 1915 to the A. M. A. meeting, the San Francisco Exposition, Honolulu, the Philippines, China, and Japan.
Examination for Anatomist in the Army Medical Museum.—The United States Civil Service Commission announces an examination for anatomist, men only, on January 7, 1914, and upon the list of eligible persons obtained from the examination it is intended to fill a vacancy in this position in the Army Medical Museum, office of the Surgeon General, United States Army, at a salary of $1,600 a year. It is desired that the person appointed to this position have a good knowledge of anatomy, general physiology, histology, bacteriology, embryology, general pathology, general medicine, having a thorough knowledge of pathological anatomy, pathologic histology, pathology, and bacteriology, and be capable of making photomicrographs, understand microscopes, surgical instruments and appliances, and be able to operate on the dissecting-room museum specimens. For further information regarding the scope of the examination and for the necessary application blanks, address the United States Civil Service Commission, Washington, D. C.

Hospital Efficiency.—At a conference held in Philadelphia on December 30th, which was attended by representatives of many of the hospitals of that city, an efficiency engineer laid before the conference a proposal to organize a central cooperative purchasing department through general which should be obtained all the supplies for the hospitals subscribing to the movement. This engineer said that such a central bureau would make possible great economy in the operation of the hospitals. The bureau would also standardize various details in the operation of the various hospitals, thus effecting a uniformity in salaries, etc., that would be done only at the expense of a higher degree of efficiency. It was stated that the sum of $7,000 would be required to make a preliminary survey. The following hospitals were pledged to cooperate in the enterprise: Pennsylvania, Pennsylvania Hospital for Children's Homeopathic, Kensington, Jewish, Children's Hospital of Philadelphia, Howard, Mt. Sinai, Rush, University, and Gynecian.

National Institute of Social Sciences.—On December 20th, the president of the American College of Surgeons, a gold medal of honorary membership, and the presentation medal of the National Institute, for notable service to humanity, were presented to Sir Richard J. Godlee, president of the Royal College of Surgeons, England, and a member of the National Institute of Social Sciences: Dr. George E. Brewer, Dr. Philip van Ingen, Dr. Linsky R. Williams, Dr. William B. Coley, and Dr. Virgil P. Gibney, of New York; Dr. J. M. T. Pinney, of Baltimore; Dr. C. W. Stokes, of United States Navy, Washington, D. C.; Dr. G. E. Armstrong and Dr. Walter W. Chipman, of Montreal; Dr. Franklin H. Martin, of Chicago; Dr. George W. Cline, of Cleveland, and Messrs. B. Aymar Sandis, of New York, and K. L. Turpin, of Southamp ton, England. It was voted to include in the minutes of the journal of the institute, the speech of Hon. Nelson T. Aldrich, and the address of Albert Shaw, Esq. The date of the general meeting was changed to the third Friday in March.

H. Hope Gambrill Curtis, secretary.

Expectoration from Elevated Car Windows.—Spitting in public places is now generally recognized to be insanitary and in certain cases even dangerous to the community. It is prohibited by section 178 of the Sanitary Code, the provisions of which are very generally upheld by public opinion, and it can be confidently stated that the publicity from time to time given to this section by arrests for its violation has caused a very considerable diminution in its frequency at one time commonly expected. Occasionally, however, as in the case which follows, the department fails to secure the punishment of the offender. In this instance, the violation was of that portion of the section which prohibits spitting into the streets from the cars, and was observed by an elevated railroad detective in uniform, one of the sanitary squad of the department, while riding on a Third Avenue elevated train, noticed a man spitting from the car window into the street and caused the offender to be arrested. He then continued to spit in a newspaper and later again expectorated from the car window. He was thereupon arrested and sent to court. The man was discharged. The records of the department showed that the man was suffering from tuberculosis of the lungs in the third stage, and that his sputum, previously examined by the department, contained tubercle bacilli.

Pith of Progressive Literature.

DEUTSCHE MEDIZINISCHE WOCHENSCHRIFT

October 2, 1913.

Sodium and Potassium Metabolism in Diabetes mellitus.—S. Kohn asserts that in diabetes the amount of potassium in the organism is increased, and that of the sodium decreased. There is a strong resemblance of the symptoms of potassium poisoning to those of diabetes; glycosuria is observed in increased potassium and decreased sodium administration. The cause of this metabolic disturbance lies in faulty gland functioning of the pancreas. The oatmeal cure now in vogue is justified by this theory.

Chloroform and Ether Narcosis, the Value of Narcotic Apparatus, and the Support of Inhalation Narcosis by Morphine, Scopolamine and Certain Soporifics.—M. Kochmann says that narcotic experiments in animals with chloroform and ether have in all essential points confirmed the practical experiences of the surgeons. The author has discarded all inhalation apparatus. When chloroform and ether are mixed in the proportion of one to six or seven, a strong narcotic action is observed; all other proportions of the mixture only add a secondary effect. A previous dose of morphone increases the narcotizing action of chloroform in the proportion of 100 to 163, in ether in the proportion of 100 to 150, by diminishing the concentration of the drug necessary for narcosis. The combination of chloralhydrate and veronal with chloroform is slightly unfavorable, somewhat less than with ether; paraldehyde appears to be the least harmless.

Treatment of Cardiac Failure in Pneumonia with Veneesection and Adrenalin Sodium Chloride Solution.—Lonhard reports the recovery of an almost fatal case of asthenic wandering pneumonia (commencing pulmonary edema; temperature, 41° C.; pulse, 140; respirations, 58) after a venesection of 300 c. c. and three injections of sodium chloride adrenalin infusion.

Cymarin in Chronic Myocarditis with Decompensation.—R. Kolb found that intravenous injections of cymarin (ampoules containing 1.2 c. c. of the solution, equivalent to 1.2 milligrammes cymarin) produced gratifying results in severe cardiac insufficiency with chronic interstitial nephritis which had resisted treatment with digitalis, camphor, and caffeine.

Experiences with Kordalen Injections.—Koebel reports that the action of kordalen in failing compensation resembles closely that of digitalis. But its subcutaneous injection is not as painless as the pharmaceutical firms would have us believe. The author had a case in which four weeks after injection a large, very painful infiltrate still existed.

Fourth Report on Behring's Diphtheria Vaccine.—Kleinschmidt and Vierbeck report that the best method of administering Behring's diphtheria vaccine is the intracutaneous injection, for which purpose 20 to 25 milligrammes, in a two per cent. solution, are sufficient. In the beginning of the reaction four stages are to be distinguished; 1, 2, 3, 4.
erate redness and infiltration (diameter from one
to two centimetres); 2, marked redness and infil-
tration (diameter over two centimetres), with pain
and then abeyance of it; 3, inflammation of the
neighboring lymph apparatus; 4, general symptoms,
as fever, etc. The result of the immunity is judged
by the diphtheria antitoxin in the blood which
should be repeatedly controlled by Römers or
Schick's method on the guinea-pig. The presence
of an antitoxin of 1/20 È in one c. c. of blood is a
sufficient protection even in severe infections. The
effect of the active immunization begins at the very
earliest on the eighth day after the injection.

Experiences with Radium Therapy in Internal
Disease.—F. Kraus says that the best results with
radium therapy were obtained in sciatica, subacute,
and chronic; cases of rheumatism also showed
marked improvement; the same could be said of
gout, arteriosclerotic manifestations and, at times,
the results of brain hemorrhage. The intramuscu-
lar injections gave the best results; in many selected
cases their combination with diathermia seemed to
be of particular advantage.

Protein Content in the Sputum of the Tubercu-
losus.—E. Gelderblom asserts that the presence
of protein in the sputum of tuberculous patients is
proof of the presence of a fresh process in the lung;
an increase or decrease of the protein amount indi-
cates the spreading or improvement of the process.
The amount is determined after the Pindborg
method with the aid of Aufrecht's albuminimeter.

Ischias cyphotica.—Johann Hnátek describes a
case of typical right sided ischias which accompa-
ied a cyphosis of 120°; it disappeared with the
primary condition. The rare occurrence of a cy-
photic sciatica, there being only three similar cases
in the literature, is accounted for by a diseased sen-
sory branch of the sciatic nerve in the sacroiliac
muscle, the latter also pressing on the nerve by its
contraction.

The Rupture of an Aortic Aneurysm into the
Upper Vena cava.—A. Klein reports that sud-
den death was preceded by a high grade of
dyspnea, edema, and cyanosis of the head, neck, the
upper extremities, and of the upper portion of the
thorax to the height of the xiphoid process. In the
literature seventeen similar cases are found.

Progress of the Silver Treatment in Gonorrhea
of the Male.—E. Rosenfeld recommends for the
abortive treatment of gonorrhoea three injections of
0.1 per cent. solution of hegonon, retaining each
for five minutes; these injections are repeated at in-
tervals of from three to five days, each combined
with a Janet's irrigation with a solution of from
one in 3,000 to one in 1,000 for the same length of
time. Advanced cases require from four to six in-
jections daily. When complications are present, be-
sides the treatment with hegonon solution, an active
immunization is urged by injections of polyvalent
gonococcus vaccine, or by arthigons. The results
are excellent. Hegonon is a compound silver ni-
trate-ammoniac-albumen, and it differs from other
silver preparations in its extraordinary nonirritat-
ing quality.

Jos. Koch concludes by saying that lyssa in his part
of the country may be considered a rare occurrence.
There are without doubt cases of abortive lyssa
chiefly of the spinal and cerebral type which
end favorably. The characteristic finding in true
lyssa are Negri's bodies in Ammon's horn, having an
intracellular position and peculiar inner bodies, and
the smallest cocci-like forms in all of the gray matter, and in the
ganglion cells of the spinal cord and brain situated in
the gray matter. Noguchi, it is claimed, has
recently grown the latter cocci-like bodies anerobic-
ally. There are, in all probability, latent lyssa infec-
tions in which the virus remains latent in the cen-
tral nervous system—incubation period—and is
aroused to its fatal activity by some contributory
cause as trauma, etc. For these cases medicinal
therapy is indicated. Iodine in the form of solu-
tion of potassium iodide four in 200. Vaccination,
however, remains the conditio sine qua non.

Abderhalden's Dialysis in Psychiatry.—Bund-
schuh and Roemer examined the brain cortex, thy-
roid, and genital organs, and sometimes the kidneys
with the usual controls; serum alone, and organ sub-
stratum plus inactivated serum were all negative.
Nine normal subjects reacted negatively, and also
nine manic depressives. Forty-one cases of demen-
tia precoex split up brain cortex thirty-five times,
genital organs thirty-four times, thyroid fourteen
times. Thirteen paralytics gave positive reactions,
fourteen times with brain cortex, twice with tes-
ticle; and negative reactions, twice with brain cor-
tex, ten times with testicle, and in every case with
thyroid.

Tubercle bacilli in Blood.—C. Moeves and
Brüttigam have shown that the various staining
methods for blood smears now in vogue are not re-
liable. Animal experiments with the blood of fifty
patients suffering from tuberculosis did not reveal
in a single case the presence of tubercle bacilli. It
may be assumed that in miliary tuberculosis bacilli
circulate in the blood only temporarily.

Animal Experiments on the Presence of
Tubercle bacilli in Tuberculosis of the Skin,
Particularly of the Face.—K. Stern found in 68.7
per cent. of the cases the presence of virulent tub-
ercle bacilli in the excretions of ulcerating lupus
(by animal experiments). It follows that a patient
with ulcerating lupus is a source of infection for
himself and others; he should for this reason be
isolated.

Zone Degeneration in the Liver of Pregnancy.
—P. Heinrichsdorff considers with Opie under this
term a uniform toxic affection producing a uniform
necrosis in certain parts of the whole liver, the cen-
tral or peripheral, or central and the intermediary
zones of the liver lobes. They report a puerperal case
in which the microscopical examination of the liver
revealed a high grade of degeneration in the central
and intermediary zones. In each case we must de-
cide what relation exists between these areas of
necrosis in the liver and a concomitant or ended
pregnancy.

Three Cases of Patent Ductus Arteriosus
Botalli.—Motsfield's three post mortem examina-
tions on two men, aged thirty-two years and thirty-
five, and on one woman, aged fifty-five, showed
a patent ductus, although in life they had so few
symptoms that a positive diagnosis of this condition could not be made.

October 22, 1912.

New Therapeutic and Prophylactic Experiments in Gonorrhea.—C. Brück recommends the use of cabiven rods, made by melting the tube-like shells which contain uranoblen in powder form. Uranoblen is a forty per cent. combination of silver with uranin. Although uranoblen is almost non-irritative, in its use it is best to await the cessation of all acute manifestations. After treatment lasting fourteen days, the patients were permanently free of gonococci.

Practical Results with Cabiven Therapy.—A. Sommer says, in the application of cabiven therapy in male and female urethral gonorrhea, in cervical gonorrhea, and the gonorrheal vulvovaginitis of small girls, the excellent results of the method are enhanced by its simplicity. The gonococci frequently disappear from the microscopic field after one application and almost always after a few insertions of the rods. For anterior treatment a straight rod twice daily is introduced; for posterior treatment every third or fourth day a longer, specially curved rod is introduced. Patients should be warned that the preparation stains.

Biological Studies of Gonococci, with Special Attention to Uranoalen.—A. Gluck asserts that uranoblen is an uncommonly safe means of killing gonococci; it has this property in a concentration which is ten times weaker than the therapeutic dose.

Benzol Therapy in Leucemia.—E. Mühllmann reports the case of a man, thirty-seven years old, with lymphatic leucemia, which was favorably influenced at certain times by combining treatment with benzol and thoriun x therapy. Death ensued after six months, and the autopsy revealed widespread liver necroses.

October 29, 1912.

Further Experiments with Abderhalden's Diallysis in the Insane.—J. Fischer found in those suffering from dementia precox that the genital glands were split up without exception, more specifically the testicle in men, and the ovary in women; the brain cortex was almost constantly split up. In sixteen cases of genuine epilepsy the brain cortex was reduced only once. In examining ten paralytic he found that the brain cortex was invariably split up, the other organs less frequently, and the genital organs never. The author suggests that it would be well in the future to make a note of the mental state of the patient in the history, at the time of making the blood test, particularly a note as to the mood.

Thymin and Its Action in the Treatment of Basedow's Disease; and Thymin as a Soporific.— R. Hirsch reports that thymin tablets are made from the thymus gland of the calf. Two tablets (0.5 grammme) daily were given under the supposition that the thymus effects hyperfunction or painful function of the thyroid. The results, consisting of an improvement in restlessness and sleeplessness, regression of the struma, exophthalmus, and cardiac disturbances were marked; an improvement was noticed in two cases in which operation had been without effect. As a soporific, thymin given in doses of one or two tablets in certain cases of diabetes insipidus, neurasthenia, arteriosclerosis, and dyspepsia, has also produced good effects. No untoward action was noticed. In animal experimentation, two doses of thymin of 0.5 gramme each, daily, produced an increase of the nitrogen metabolism and the calory production.

PARIS MÉDICAL.
November 22, 1912.

Aseptic Empyema.—C. Dopter reports a case of croupous pneumonia and another of broncho-pneumonia complicated by pleural exudate, in which exploratory puncture yielded a seropurulent fluid containing numerous well preserved leucocytes and a few endothelial cells, but no bacteria. Cultures and inoculations of rats gave negative results. A third case was one of acute lung congestion in a frankly tuberculous patient, complicated by empyema, with thick grayish pus containing, however, neither tubercle bacilli nor other organisms. In a fourth case, an attack of grippe was followed by pulmonary congestion, aural pain, and mastoid tenderness, sepsis and tuberculous discharge containing pneumococci from the ear, and a septicemic decrease of temperature curve; intrapleural exudation was soon noted, but the pus proved sterile. In none of these cases was surgical intervention resorted to as regards the chest; yet recovery always promptly followed—after a mastoid operation in the last case. Discussing aseptic empyema in general, Dopter points out that while the leucocytes in the pus may finally show evidences of senescence, there is never the total degeneration and nuclear deformation and pallor of these cells that is seen in septic pleural exudates. The advisability of recognizing these aseptic purulent exudates lies in the fact that their evacuation is contraindicated, unless they are extensive.

Vaccine Treatment of Complications of Gonorrhea.—P. Remlinger reports excellent results from the use of an atoxic antigonococcal vaccine recently described by C. Nicolle and L. Blaizot. Fifteen cases were treated, and a detailed history of six of these is given. The vaccine was injected under the abdominal skin daily or on alternate days in doses of three to fifteen drops, diluted with from two to five c. c. of normal saline solution. Pain in gonococcal orchitis and rheumatism, even where previously unrelieved by morphine, was not infrequently controlled within a few hours after the first injection, disappearing entirely after the second or third. Fever subsided almost as promptly, and the general condition showed rapid betterment. Joint swellings, thickening of the ends of the bones, epiphyseal enlargement and induration, and purulent processes in the urethra or bladder were the last manifestations to disappear. The treatment seemed equally effective whether begun at the commencement or the course of the disease or some time after. Even ten or fifteen drop doses caused no general reaction, and the local reaction, consisting of slight redness and pain, was so insignificant, compared to the testicular or joint pains, as usually to pass unnoticed by the patients. Keeping the vaccine for two months on ice did not seem in the least to impair its therapeutic activity.
Erythema nodosum and Tuberculous Septicemia.—L. Landouzy has maintained for some time that erythema nodosum is the result of a tubercle bacillus septicemia, basing this conclusion on the frequency with which tuberculous manifestations precede, accompany, or follow the eruption, but not being able to supply bacteriological proof of his assertion. He now reports the case of a female servant aged twenty-seven years with typical erythema nodosum, arthralgia in the lower limbs, fever, gradually increasing mitral insufficiency (endocarditis), signs of congestion at the right pulmonary apex, and a positive tuberculin reaction, in which a typical tubercle bacillus, with diffuse inflammatory lesions, especially of and around the vessels, was discovered in a nodule taken from the forearm. Injection of part of the same nodule into a guinea pig gave positive results.

**Paroxysmal Dyspnea in Cardiorenal Patients.**—Thomas Lewis, through his work on cardiac cases, has had his attention drawn to the frequent occurrence of severe dyspnea in many patients, in whom there has been little or no cyanosis and often only very slight cardiac disturbance. A searching study of these patients, by him and his coworkers, has led to the discovery of the cause of the dyspnea, which has been found to be due to a relative acidosis of the blood. The special clinical associations of this relative acidosis are given. While these are the most constant clinical manifestations, they are usually complicated to a greater or less extent by the simultaneous association of cardiac or renal symptoms, or even by symptoms of uremia. The types encountered are, therefore, protean, and in many cases there is, in addition to the dyspnea of acidosis, a dyspnea due to deficient aeration of the blood. The mechanism of the heart may be disturbed in any of the known ways, and the urine may show signs of the most severe grade of nephritis. In all of these cases, whether complicated by deficient aeration of the blood or not, it has been found that there is a greater or less degree of relative acidosis. The test of the acidosis is the degree of saturation of the hemoglobin with oxygen when it is exposed to a known and definite oxygen pressure. Physiologists have long known that the introduction of acids into the blood causes hyperpnea, whereas alkalies cause apnea. Deficient aeration produces dyspnea through the accumulation of carbonic acid: violent exercise by the accumulation of lactic acid; diabetes through the presence of beta oxybutyric and allied acids. The acids which accumulated in the blood of the patients studied by Lewis have not been identified as yet, but their presence is demonstrable, and their discovery clears up a problem long unsolved. It is no longer justifiable to use the terms, cardiac, renal, or uremic asthma. The condition in each case is due to acidosis, and should be spoken of as "asthma of acidosis." It is possible to subdivide asthma of acidosis into different etiological groups, depending upon the acid present. In the types of cases studied the ultimate outcome of the condition has been more or less rapid progression to death. It is possible, through diet and other measures of treatment directed to the relief of the associated conditions, to prolong life and ameliorate the dyspnea in many of the cases. The use of carbonates seemed to offer a hopeful means of treatment, but actual experience has shown them to be of little value. The treatment is only palliative at best.

**Clinical and Bacteriological Aspects of Leprosy.**—H. Bayon cites the growing belief in the absence of contagious properties of leprosy and relates the following substantiated observations as establishing its contagiousness: 1. It is due to a definite microorganism. 2. In regions previously free from leprosy it was found to spread concentrically from the first imported cases. 3. Practically all the cases originate in countries in which the dis-
ease is common. 4. Rare cases occurring in countries in which the disease is not indigenous can in every instance be shown to have been in more or less prolonged contact with lepers, or to have occurred in leprosy regions. 5. The disease is found to be limited to families, or to small foci, in countries where there is little leprosy. 6. The disease has gradually and constantly diminished in those countries in which there has been universal segregation of lepers. 7. On the other hand, where segregation has not been adequately carried out there has been a continual increase in the disease. It has also been conclusively proved that the incidence of the disease in families is greater by far than in the general population. The belief that doctors and nurses who have been in charge of lepers for many years never contract the disease is ill founded, for there are not a few such persons who have become leprosy. Animals can be infected. In the face of this evidence it is impossible to believe that the disease is not contagious, and there is no evidence to suggest the probable transmission of the disease from man to man by means of any insect carrier. The disease is, however, not very readily transmissible, and it is probable that more or less prolonged and intimate contact is usually required for infection. In the face of these facts the need for segregation of lepers becomes absolute, particularly as there is, as yet, no known treatment of the disease which can be regarded as offering much hope.

Lancet.
November 29, 1913.

Tuberculous Meningitis in an Infant.—George A. Allan's patient died when just twelve weeks old. The infant was apparently normal at birth, was nursed by his mother, and thrived for the first six weeks. At about this time he was given two feedings of diluted cow's milk daily to supplement the mother's nurseries because he was not progressing well. Two weeks later a cough developed and moist râles at the bases of his lungs, both of which disappeared after simple treatment. Cow's milk was discontinued. At the age of eleven weeks he was only about the same weight as at birth, he was pale and irritable, and he had an eruption on the legs simulating lichen. His head became retracted two days later, and from then till the end, five days later, he showed typical signs of meningitis of a subacute type. A post mortem examination showed the presence of generalized miliary tuberculosis, involving particularly the spleen and liver, and a tuberculous meningitis. From both spleen and the spinal fluid tubercle bacilli were isolated and cultured. They were determined to have been of the bovine type, and animal tests confirmed this finding. Allan is of the opinion that the infant did not become infected from the two weeks' use of cow's milk, but rather from contact with his brother, who was the subject of tuberculous adenitis, and who may have had an open focus in his mouth.

Free Air Treatment of Skin Grafts.—A. Roycin Jones reports excellent results with this method in a series of twenty-six consecutive cases, only two requiring a rep-tition of the operation. The average time required for healing is about three weeks, and no local application whatever is made to the grafted area during this time. The only attention given the region, besides its protection under a sterile wire cage and light cotton dressing, is the occasional removal by forceps of the hard, black crusts which form between the grafts.

Eye Coloration in Relation to the Incidence and Severity of Scarlet Fever and Diphtheria.—A. L. Dykes cites Biemacki as believing that children with light eyes are more susceptible to severe diphtheria than are others, and that the disease is more fatal in them. Others have also shown that there is a relation between pigmentation and susceptibility to disease. Epilepsy and skin diseases seem to be commoner in the brown eyed, while light eyed persons are more susceptible to rickets. As a means of classification of eyes, Dykes accepts three types: 1. The simplex, in which the eyes are blue and gray with no stroma pigment visible. 2. Duplex medium, in which the eyes show variable amounts of visible stroma pigment on a background of blue or gray. 3. Duplex dark, showing a large amount of stroma pigment, the iris being brown. For comparison the color of the eyes has been recorded in 1,153 school children from four to twelve years of age. Roughly, there were thirty per cent. in the simplex group and thirty-six per cent. in the dark duplex, with the duplex median numbering about thirty-four per cent. In 679 cases of scarlet fever the proportions were about thirty-two per cent. simplex and thirty-eight and a half per cent. duplex medium, with the duplex dark numbering only a trifle more than twenty-nine per cent. The proportion of severe cases and of deaths stood highest among the light eyed group, decreasing to its lowest among the duplex dark group. The same findings were obtained in a study of diphtheria, the greatest morbidity, severity, and mortality occurring among the simplex and the lowest among the dark duplex groups.

Shock.—G. W. Crile says there is a group of organs whose function is the conversion of potential into kinetic energy. These organs form a kinetic system, and among them are the brain, the thyroid, the adrenals, and the muscles. The kinetic system converts latent energy into motion or heat in response to adequate stimuli. If the stimuli are overwhelmingly intense the kinetic system—especially the brain—is exhausted, even permanently injured. This condition is acute shock. If the
stimulation extends over a period of time, and is not so intense as to cause an immediate breakdown or acute shock, its repetition may cause the gradual exhaustion of the kinetic system, and this condition may be called chronic shock. Either acute or chronic shock may be measurably controlled by weakening or breaking the kinetic chain at any point. This has already given us the shockless operation, and it opens a possibility of controlling certain chronic diseases of that intensely kinetic organism, civilized man.

Note on a Mould, Cocciidioiides immitis, Found in a Case of Generalized Infection in Man.—W. J. MacNeal and C. E. Hjelm report that in a case of systemic blastomycosis described by R. T. Morris in this issue of the Journal plate cultures on ascetic fluid agar of pus obtained from an incised subcutaneous abscess, brought to development, after incubation for forty-eight hours, numerous colonies of radiating mycelial threads, the appearance of which suggested the possibility of oidioamycosis. On the plate cultures of a second specimen of pus, obtained two days later, by aspiration from a closed subcutaneous abscess, many colonies of mould developed, apparently in pure culture. From the characteristics shown by this mould the authors regard the organism as identical with that discovered by Posada and Wernicke and first described in this country by Rixford; in two cases, and subsequently studied by Rixford and Gilchrist, who gave it the name of Cocciidioiides immitis.

Some Intraabdominal Complications Following Laparotomies.—A. E. Benjamin refers first to preexisting derangement of the functions of the alimentary canal, and speaks of the importance of a prolapsed stomach and colon. With adhesions around the pylorus, there may result dilatation of the stomach which interferes with the large and small bowel action. In such cases the outcome may be general intraabdominal tension, which forces the coils of intestine into close contact, and, in the presence of infection or of any raw or denuded surfaces, adhesions necessarily follow which may be temporary or permanent according to the circumstances present. He then takes up the following points: Mucous colitis and membranous peri-colitis; state of the muscle tone of the abdominal wall; character of infection; raw surfaces or denuded areas left within the abdomen after operation; removal of appendix; operative traumatism; undue exposure of the viscera; foreign substances; drainage; closure of the peritoneum and of the abdominal wall. In speaking of postoperative management the author says that in acute gastric dilatation the stomach tube should be used at the earliest possible moment; a procedure which will save many lives and go a long way toward preventing the adhesions which follow in the wake of operations. Great care should be observed in the regulation of the diet, and the position of the patient should also be considered. If there has been extensive pelvic work done not requiring drainage, and especially if there has been a prolapsed stomach, elevating the foot of the bed will assist restoration of position and function of the stomach and intestines; often obviating the possibility of adhesions within the pelvis.

Erysipelas—Clinical Observations on 800 Cases, Including Ninety-five Treated by Bacterial Vaccination and Twenty Treated by Phylacogen.—S. Erdman reports that in this series there were ninety-three deaths, or 11.625 per cent. His experience with vaccines shows that the duration of the disease was not at all shortened, the mortality remained at the same level, and there was no immunity guaranteed against recurrence or against spreading of the lesion; nor were complications, such as cellulitis and abscesses, prevented. From the statements furnished by the patients, moreover, he could not gather that there was any amelioration of the subjective symptoms. The same facts were true as regards the use of phylacogen.

MEDICAL RECORD.

December 6, 1913.

The Serological Tests in Cerebral Hemiplegia.—C. L. Dana states that for two years he has been having patients at Bellevue Hospital with cerebral hemiplegia submitted to serological tests, in order to determine whether there was a syphilitic or inflammatory element in the case. The attempt was made to have four tests in each case: A Wassernann test of the blood serum and of the cerebrospinal fluid, a globulin test of the spinal fluid, and a cell count of this fluid. Either complete or partial tests were made in twenty-eight cases of acute hemiplegia and in twenty-six cases of old hemiplegia—of at least six months' standing. The conclusion reached was that in the hospital cases of acute cerebral hemiplegia there was a putic infection in about fifty per cent. This proportion of lues in hemorrhage of the brain was surely much higher than in the nonhospital cases, and the figures were not extensive enough to justify final conclusions. Probably in some instances the infection was incidental, and had nothing to do with the lesion. In the chronic cases the reactions were much less marked than in the acute, and this might be due in part to the fact that nearly all such patients received iodides and mercury after their seizures. It would not be unfair to conclude from a study of thirty-seven consecutive cases in which the Wassermann test was employed that in nearly half of hospital hemiplegia there was a putic infection present.

Colds and Their Relation to the Physics of the Atmosphere.—From his study of this subject C. M. Richter concludes: 1. Acute coryza, commonly called a "cold," depends for its development primarily on an excess of moisture in the air we inhale. 2. It develops, therefore, principally during the cyclonic weather condition called low, especially when a period of very dry weather has preceded this and when, in consequence, the change to the incoming very moist air is most rapid. 3. The excessive and more or less continuous nasal secretion at the beginning of an acute coryza relieves the respiratory apparatus from the otherwise damaging effect of an overcharge of moisture. 4. A child's nasal mucosa and the hyperesthetic ones are especially prone to suffer. 5. The running of the nose constitutes in part a physiological vasomotor action analogous to the profuse and more or
less continuous perspiration of the outer skin which sets in whenever air temperature and relative humidity overstep certain limits and which forces thereby better conditions for evaporation. 6. Latent microbism becomes active on the mucosa only after these air conditions have favored its development for some time. Microbism is very rarely the primary cause of an acute coryza.

Gumma of Prostate and Bladder; Six Intravenous Injections and One Intramuscular Injection of Salvarsan and Twenty-six Intravenous Injections of Neosalvarsan to Patient Sixty-six Years Old.—J. Q. Rush reports this case. The results were gratifying, and the disappearance of albuminuria and edema under the treatment leads him to think that, in addition to the involvement of the prostate, there was considerable damage to the kidney, due to syphilis. His conclusions are as follows: 1. Neosalvarsan should be given in larger doses and at shorter intervals, covering a period of at least one year in all cases of tertiary syphilis. 2. In cases of gummata, neosalvarsan, alternated with mercury hypodermically, should be given for a period of not less than one year; the neosalvarsan injections should be given, if possible, not more than seven days apart. 3. The negative Wassermann reaction should not prevent the continuation of treatment in cases in which benefit is noted from its continuation. 4. In cases of gummata the Wassermann reaction may often be faintly positive or negative when the lesion is of a serious nature and demands prolonged and consistent treatment.

Tuberculosis and the von Pirquet Test in Children.—L. Shalet holds that a persistent negative von Pirquet test in a child, excepting those in whom the test is negative even in the presence of tuberculosis infection, just as surely excludes the diagnosis of tuberculosis as a positive sputum confirms it. He has come across a considerable number of cases in children which have been definitely diagnosed as tuberculous, on the presence of a few physical signs accompanied by some temporary fever, so common in children; on the strength of which diagnosis these children have been sent to the same public sanatorium. On their return, however, usually in about six months, the von Pirquet test, done as a routine measure, has been found to be negative. He therefore suggests that a rule be laid down that no ambulant case of possible tuberculosis in a child under sixteen years be diagnosed as such unless the patient reacts positively to the von Pirquet test.

JOURNAL OF MEDICAL RESEARCH
October, 1913.

Experimental Streptococcic Arthritis in Monkeys.—Schloss and Foster, instead of using rabbits, made their experiments on Rhesus monkeys because they are larger and more resistant animals and the effect of repeated injections could be observed. They used a strain of Streptococcus pyogenes hemolyticus, which had been grown from the tonsils of a patient with acute arthritis. In four monkeys it induced a polyarthritis, suggestive in certain respects of "rheumatic fever" in man. The infecting organism could be recovered from the blood stream at the onset of symptoms, but not afterward. This fact possibly has some bearing on the failure to isolate organisms from the blood of man with rheumatic fever. Repeated inoculations of streptococci induced a chronic arthritis in two cases, which was manifestly by limitation of motion and contracture.

The Presence of Tubercle Bacilli in the Feces._—Laird, Kite, and Stewart review briefly the work that has been done along this line. They then report the result of their examinations. They found that of the one hundred and one specimens of feces from patients with tubercle bacilli in the sputum, sixty (or fifty-nine per cent.) showed the presence of acidfast bacilli. Of the forty specimens which did not show them, seventeen were from patients who had no tubercle bacilli in the sputum at the last examination previous to the test or else had ceased to have expectoration. Of the fifty-four specimens of feces from patients without tubercle bacilli all but two (or ninety-six per cent.) were from from acidfast bacilli. Inoculations of feces containing acidfast organisms were made into guinea-pigs. Out of sixty cases in which the guinea-pigs lived long enough for tuberculosis to develop, forty-eight (or seventy-seven per cent.) showed positive macroscopic lesions at autopsy. Of guinea-pigs inoculated with feces free from acidfast bacilli ninety-five per cent. showed no tuberculous lesions. It is, therefore, evident that nearly all patients with tubercle bacilli in the sputum also have virulent tubercle bacilli in the feces; also that very few persons who do not have tubercle bacilli in the sputum have acidfast bacilli in the feces.

SOUTHERN MEDICAL JOURNAL.
October, 1913.

Epitheliolysis against Carcinoma; Preliminary Note.—A. E. Thayer relates the history of his experimental work, begun in 1906, and reports a case of inoperable carcinoma of the cervix treated with remarkable results during the past summer. While it is too soon, of course, to announce that this case has been cured, though the patient's response to treatment has been so rapid and apparently successful, he regards as proved the working hypothesis that the serum may be rendered lytic by repeated injections of an autolyte of epithelium, and, what was expected as the result, namely, that the intimate microscopic medication of cancer cells from within by an all pervading, ever-preent chemical agency, not injurious to the body's normal epithelium, would affect favorably both the main tumor and also its metastases, however minute, has seemingly taken place in this case. All that may safely be asserted on the basis of this one case, the author says, is that there has been a prompt and so far very encouraging response; but if the time arrives when the patient may be discharged as cured, and other cases show improvement of varying degrees, then he believes the problem will have to be restated and worked out again for the sarcomas, which, in his opinion, is a far more difficult and complicated task. Beyond these there is a group of other pathological conditions, such as Hodgkin's disease, with abnormal hyperplasias as an important element in the
lesion, where a somewhat similar line of reason-
ing may perhaps be employed to advantage.

The Nonmedical Treatment of Chronic Consti-
pation.—F. W. Wilkinson, as an aid in the treat-
ment, reviews the etiology, only the nonmechan-
ic factors being considered. These may be classi-
ified as: 1. Heredity; 2. age, occupation and sex; 3.
intestinal atony and loss of tone in the abdominal
muscles; 4. irregular habits of going to stool; 5.
improper diet; 6. inflammations of the bowels, more
particularly the ceum, sigmoid, and rectum; 7. af-
fecfions of the nervous system, lead poisoning,
tubes, and psychic influences. The nonmedicinal
treatment resolves itself into two varieties—the ed-
cational and prophylactic and the treatment of the
condition after it has become established. In the
latter the diet is one of the most important factors,
and many cases can be cured by a properly selected
dietary alone. Having given a list of the permitted
foods, the author says that of all the articles named,
those having the most marked laxative effect are
water, cracked wheat, bran biscuit, coffee (for
some), fruits, green vegetables, and oils. The
principal other agencies to which he refers are exer-
cise (especially in the open air), hydrotherapy in
its various forms, and abdominal massage. Me-
chanical vibration is often helpful, though not so
useful as manual massage. Psychic treatment alone
will cure certain cases due to hysteria, and in all
cases we should use the power of suggestion to keep
the patient in a hopeful frame of mind. The first
requisite in the successful treatment of chronic con-
stitution is a correct diagnosis; this having been
made, persistence in the following of some or all
of the measures outlined will be crowned with suc-
cess in the majority of instances.

A Description of Ainhum as Seen in the Canal
Zone, with Report of Interesting Cases Occurring
in One Family.—Henry Weinstein defines ainh-
um (Dactylolysis spontanea) as a tropical disease
of great chronicity, generally limited to African and
East Indian peoples, which is characterized by
spontaneous amputation of the little toe of one or
both feet, although very rarely other toes may be
involved. A most characteristic feature, and, in-
deed, a pathognomonic sign of the affection, is a
peculiar constricting ring formed over the affected
toe or toes. Pathologically ainhum presents marked
trophic changes in the diseased parts. The con-
stricting ring is made up of dense fibrous connective
tissue covered by a layer of epidermis. The sub-
cutaneous tissue is increased at the expense of
muscle, tendon, and soft parts, while here and there
may be seen islands of fat cells. Blood vessels are
everywhere numerous, and in the bone there is a
condition of rarefying osteitis. Eventually, the
highly organized tissues such as sweat glands, blood
vessels, muscles, and bone are changed into con-
nective tissue, and in all there are evidences of
impaired nutrition, due to pressure, and vasomotor
and trophic manifestations. Although in some re-
spects it resembles scleroderma and leprosy, one
must conclude that ainhum is a distinct disease—a
special trophoneurosis. In the cases described by
the author the family history revealed a strong
hereditary tendency affecting all females in three
generations and apparently transmitted by the male
progeny.

Surgery, Gynecology, and Obstetrics.

October, 1913.

Congenital Atresia of the Esophagus; An
Operation Designed for Its Cure.—H. M.
Richter states that the site of the atresia is on a
level with the bifurcation of the trachea. There
is a complete separation of the two segments of
the gullet. The upper segment ends below as a
dilated blind pouch, behind and just above the
tracheal bifurcation. The lower segment joins the
stomach at the cardia in the usual manner. The
especially fatal factor in the anatomy consists in a
communication between the upper end of the
distal segment and the trachea or bronchi, allowing
a free communication between lungs, gullet, and
stomach; forced respiration, as in crying, etc.,
distends the stomach; attempts at vomiting fill the
air passages with stomach contents (secretions),
resulting in drowning (cyanosis). The symptoms
begin immediately after birth and may be sum-
marized as follows: 1. Everything taken regurgi-
tated at once, beginning with the first attempt at
feeding; 2. continuous discharge of saliva and
mucus from mouth; 3. spells of cyanosis at fre-
fquent intervals, especially brought on by feeding;
4. the abdomen distended by crying and coughing;
5. difficult respiration, marked inspiratory retrac-
tion of chest and abdomen; 6. passing catheter into
the esophagus disclosures a complete block at
from ten to twelve centimetres from the gums, at
the bifurcation of the trachea; 7. an early rise of
temperature with cough usually indicates the
development of pulmonary involvement from the
constant regurgitation of fluids from below. The
plan of operation is closure of gullet at the tracheal
junction by the translateral route and gastrotomy.
The technic consists of a preliminary gastrostomy
under ether; intubation of the lower segment of
the gullet from below with a metal sound; change
to positive pressure, using ether anesthesia; in-
cision into the right sixth intercostal space about two
inches long, the posterior end carried upward and
the sixth, fifth, and fourth ribs cut across near their
angles; retraction of the ribs gives a perfect view
of the field of operation; a silk ligature carried
around the gullet, using the sound as a guide; in-
trapulmonary tension raised until lung came to
chest wall, when remainder of wound was closed.
Senn's gastrotomy is now completed and water is
immediately given through the tube.

Tuberculin in the Treatment of Surgical Tuberc-
ulosus.—C. G. Swenson proposes as a result of
his experience with many patients having surgical
tuberculosis and being treated with tubulin, the
following conclusions: 1. Tuberculous gland infec-
tions that have not entered the stage of caseous de-
generation have yielded to tubulin treatment. 2.
Almost all local tuberculosis may be cured under
persistent, skillful, surgical treatment, assisted by
tubulin injections properly given. 3. Tubulin
injections may be safely given every tenth or
twelfth day without opsonic work; it is preferred,
naturally, that one be guided by occasional blood
tests. 4. All tubulin injections should be given
by a reliable, clean person, and the best place for the injection is on the anterior part of the chest. 5. Duration of tuberculin treatment should be from six months to two years. 6. All hygienic treatment such as fresh air, good food, and attention to digestive organs, is of vital importance. 7. For tuberculous sinuses extending into the urinary bladder the bismuth paste injections are usually contraindicated.

Infantile Type of Uterus with Dysmenorrhea.
—T. J. Watkins, after a study of sixty cases, emphasizes the following statements: Dysmenorrhea is most often due to imperfect development of the uterus. Pain is chiefly caused by contractions of the uterus, which soften and dilate the cervix and are much like the pains of the first stage of labor. In cases of infantile uterus causing dysmenorrhea the logical treatment consists in the use of remedies to promote development. The use of the intrauterine stem is useful in such cases. The patient should be kept under supervision for months after the use of the stem pessary. The cervix should be dilated if possible before each period for some months. The stem pessary should be reinserted after one or two months if necessary. This treatment is indicated only in cases of severe type. It is, however, a poor substitute for marriage and pregnancy. In cases of excessive menstruation with clots and severe pain relief may be obtained from the use of suprarenal gland, which has lately been recommended. Suprarenal gland diminishes the action of the ovarian secretion. One three grain tablet of the dessicated gland is given three or four times daily, for three days just before, or during the early part of the menstrual period.

The Technique of Insertion of Intratracheal Insufflation Tubes.—C. Jackson asserts that practically all authorities are now agreed that the larynx should be inspected before the insertion of the insufflation catheter or tube, for the purpose of ascertaining whether or not disease is present in the larynx, and also to determine the size of the larynx so that the size of the insufflation tube may be selected accordingly, in order to make sure that there is ample laryngeal lumen around the tube for the return flow. No one capable of giving an aesthetic should hesitate for one moment about this procedure, if he will take the trouble to observe the following points: 1. The patient should be fully under the anesthetic by the open method so as to get full relaxation of the muscles of the neck. 2. The patient’s head must be in full extension with the vertex firmly pushed down toward the feet of the patient, so as to throw the neck upward and bring the occiput down as close as possible beneath the cervical vertebrae. 3. No gag should be used, because the patient should be sufficiently anesthetized not to need a gag, and because wide gagging defeats the exposure of the larynx by jamming down the mandible. 4. The epiglottis must be identified before it is passed. 6. The speculum must pass sufficiently far below the tip of the epiglottis that the latter will not slip. 6. Too deep insertion must be avoided, because the speculum goes posterior to the cricoid which is lifted, exposing the mouth of the esophagus, which is bewildering until sufficient education of the eye enables the operator to recognize the landmarks.

NEW YORK NEUROLOGICAL SOCIETY.
Regular Meeting, Held at the New York Academy of Medicine, October 7, 1913.

The President, Dr. Smith Ely Jelliffe, in the Chair.

(Concluded from page 1190.)

Dr. William B. Noyes said it was rather difficult definitely to classify a case of this kind without a better understanding of the various gradations of mental depression or excitement associated with mental changes that were not uncommonly observed about the age of puberty. The exaggeration of the normal changes frequently observed in the child at that period of life resembled certain psychoses of later life. In some children, these changes were entirely physiological; in others they were slightly exaggerated, or again we might have the extreme type, as evidenced in this case, although the symptoms might not be so sharply defined. This, perhaps, might be accounted for by the fact that here we had a child of foreign parents, transplanted to a new environment, with poor surroundings and possibly influenced by the strain of overstudy. Although the case presented by Doctor Gregory appeared to present clear cut symptoms of manic depressive insanity, in the opinion of many who frequently see pathological nervous and mental conditions during childhood, it was better explained as one of a series of mental variations, not so easily classified as Doctor Gregory stated.

Dr. L. Pierce Clark said that an accurate knowledge of the family history in a case of this character might prove a very important factor in making more definite the diagnosis here. Undoubtedly the case was rare in literature only. He had seen two similar cases, though less severe and definite. The case furnished a sad commentary upon our insufficient studies of the psychopathy of childhood. What they really ought to have was an intensive analysis of the development of physical and mental habits, the personality and character of childhood, both in normal adjustments and abnormal adaptations to psychic shocks and crises. Often enough in the past all concerned had been quite content to put even as severe a mental depression as shown in Doctor Gregory’s case into a class of physical ailments of childhood, but here a fairly defined psychotic disorder was too evident to be disproved in such manner. He saw no good reason, however, why they should strive so hard to fit adult psychoses upon such young shoulders. Would it not be better to develop their types of psychoses of childhood upon the basis of symptom complexes as they presented themselves, and gradually make disease entities as they came into a well rounded type largely independent of the nosological designations of adult psychoses? This had been one of the greatest contentions of Meyer, he believed, in his studies upon the nature of dementia praecox, and appeared to be the excellent purpose of Hoch’s studies in the development of the shut in and open personalities of the same group. No doubt psychopathic clinics in connection with the public schools, now being established in this country and abroad, would soon furnish them with a definite material
and a better knowledge of just such cases as Doctor Gregory here presented.

Dr. A. A. Brill said he could recall two cases of this type, one a girl of about seven years whom he saw at the Vanderbilt Clinic and later referred to Doctor Gregory, and the other a boy of about ten whom he saw in Doctor Gregory's outpatient department. This boy was in a very excited and maniacal state; he constantly talked about blood, which his mother attributed to the fact that he had seen some chickens slaughtered. The whole picture presented, besides the maniacal state, a certain phase of obsession of the compulsion neurosis type. The little girl, although evincing an unmistakable maniacal phase, also presented some hysterical features, and suffered besides from a somewhat severe gonorrhoeal infection. Doctor Brill asked whether there was any question of hysteria in these cases.

Dr. B. Onuf said that in cases of this kind the question of heredity was a very interesting one to follow up. His own observations had led him to believe that in psychoses of this character, particularly in the circular cases, they not infrequently found a history of manic depressive heredity.

Doctor Gregory, in closing, replying to Doctor Brill, said he saw no grounds for calling this a case of hysteria. The child showed no evidences of that condition—no sensory disturbances nor hysterical stigmata. On the contrary, she showed all the symptoms of a manic depressive psychosis. She was very active and restless. It was of course true that these conditions, especially the mild or excited types, were apt to be mistaken for hysteria. The speaker said he agreed with Doctor Noyes that they not infrequently saw children about this age with symptoms that were merely an exaggeration of the natural moods, but here they had a child with sharply defined symptoms coming on rather suddenly. The symptoms were those of a manic depressive psychosis, and he did not see why they should not call it by that name. This girl, formerly very cheerful, met with a disappointment and became depressed and remained in this stupid condition for several weeks. Normal children would not show the effects of such a disappointment for such a length of time, and upon analyzing the case they found psychic retardation and complaints of various ailments, in spite of the fact that she was perfectly healthy. She lacked initiative, and the symptoms were typical of manic depressive insanity.

Intraspinous Treatment (Swift-Ellis) for General Paresis.—Dr. S. E. Jelliffe, in introducing a general discussion on this subject, said the year 1913 promised to be a memorable one in the history of general paresis. It was early in the year that Moore and Noguchi announced the finding of Treponema pallidum in the brains of paretics. It was demonstrated before this society at their March meeting. It was before this society, at the April meeting, that Doctor Swift and Doctor Ellis presented the details of their treatment by the intraspinous method; it was in the early part of this year that Doctor Nichol and Doctor Hough of Washington, announced the successful cultivation of the treponema from the cerebrospinal fluid in cerebrospinal syphilis, which cultivation experiments were also successfully carried out by Noguchi and others. The findings of Moore and Noguchi were verified in various quarters; they were seen in the dead and living condition, and in the dead and living tissue; the latter first by Foster, of Berlin, who obtained them from brain punctures of the living patients. Successful inoculation experiments on rabbits had been made with living brain tissue of paretics, and the results of these successful experiments had been passed on to other rabbits and the organism isolated; and the chain of evidence had practically been made complete. All this had been done within the twelve months preceding, and as a result the problem of the treatment of general paresis resolved itself down to the treatment of syphilis in a particular organ of the body, and how best could this be accomplished.

Doctor Jelliffe said that his purpose in bringing this subject to the attention of this society again, after the lapse of so short a time as six months, had been determined by a number of reasons. In the first place, it had always seemed to him that perhaps the most important function of a society of this kind, consisting for the most part of active specialist workers, should be to be on the firing line, as it were, of advance in that branch which the society represented, that subjects brought up for discussion, which had reached a fairly final state of solution, were already the property of most of the members of such a society; that when the final word had been said everybody knew it, and therefore the material presented before ceased to have that quickening and stimulating value which would come from the consideration of questions which were as yet in the state of being born. Therefore, the discussion which he had planned for the evening, and thanks for which he gave to those about to participate in it, was presented as a more or less nascent problem. If it was somewhat nebulous, if it contained more hopes and aspirations than definite records of positive acquisition, the position already outlined would be sufficient reason for bringing the matter up again. He had thought, more or less, to narrow the discussion to the treatment of paresis, because it seemed to him that here was an avenue in which a great work might possibly be accomplished, and that if attention were boldly and boldly directed toward a problem which in the past had been unconquerable, even an expression of their hope might be of value to the paretic. Certainly the valuable hints that were received at a former session of this society, in which the outlines of the Swift-Ellis method of treatment of syphilis of the nervous system has been given, should not be laid aside while there was any possibility that a turning over of the same might result in profit. Even if it was granted that the time was as yet short, that the material as yet was but inconclusive, yet certainly in the experience of some of those about to discuss the paper of the evening, and in that of others who hoped would discuss it, certain questions would arise which might be worthy of discussion. In the first place, what were some of the accidents which had accompanied spinal puncture, and the free utilization of the spinal canal? Had they been sufficiently serious to constitute a bar to its further use? Had they been sufficiently painful and disappointing to the patient to prevent their use? In other words, had they gained enough information
concerning possibilities to enable them to outline a position? On the other hand, to what source must the advantages be attributed? What was the psychic factor of a new hope, of a new method of treatment? What reliance could be placed upon the unquestionable biological improvement? How did it coincide with the clinical manifestations? How long must one wait before a clinical observation lagged behind biological suggestions, and how far did the biological data enable one to extend one's hopes of positive results? Was the optimistic attitude a justifiable one, further than the general philosophical value of all optimistic attitudes in contradistinction to all pessimistic ones? These were the questions which were of interest and which would enter into the remarks of those about to speak.

Dr. William H. Hough, clinical pathologist to the Government Hospital for the Insane at Washington, D. C., said it had now been definitely established, chiefly through serological investigation and through the finding of Treponema pallidum in the disease process by Noguchi and Moore, Le- vaditi, Foster, and others, that syphilis was an essential factor in the production of paresis, and although it was quite apparent that it was not the only factor entering into the etiology of the disease, yet their object of treatment, as in all infections, was to relieve the patient of the infectious organism. Therefore, any light that might be thrown upon the nature of the action of the infective virus might be of assistance in the treatment of the disease. This seemed especially important in the consideration of such a proctan disease as syphilis. Concerning the treatment of paresis, the speaker would consider only the intraspinous injection of salvarsanized serum, as recommended by Doctor Swift and Doctor Ellis. They should bear in mind that they were dealing with a general constitutional disease which involved the nervous system especially, and not a disease confined to the brain alone. They were dealing with a disease process which involved a vital and inaccessible part of the body, the infective agent being Treponema pallidum, probably in an especially virulent form. From his own experience with this method of treatment, which included three cases of paresis and one of cerebral lues he could make no statements as to the final results, and his object in making this report was to show that they had already obtained results which could only be interpreted as evidence of the efficiency of the treatment for the inflammatory syphilitic process, but whether they could arrest the entire paretic process permanently was still undetermined, although from the clinical improvement obtained in some cases and from a theoretical standpoint the outlook certainly seemed promising. The uniformity of the results obtained thus far indicated to him that it was the most efficient treatment for paresis that had thus far been recommended. The all important point was to institute treatment early in the disease, and this they were now enabled to do with their improved method of diagnosis. This was perhaps more important in paresis than in tabes, inasmuch as a more vital and inaccessible part of the nervous system was affected. For this reason they naturally expected, and, judging from reports, were obtaining more favorable results in the latter disease than in the former. For syphilis of the central nervous system occurring in the early stage of the disease the speaker said he believed the intraspinous injections were to be recommended, although good results could be obtained in this condition by the proper use of mercury and salvarsan intravenously. Doctor Hough said the technic he had employed was the same as that originally recommended by Swift and Ellis, excepting that after the first few injections he used forty cubic centimetres of a fifty per cent. serum, instead of thirty cubic centimetres of a forty per cent. serum. As to after effects, he had observed none of any consequence, although there was sometimes a slight elevation of temperature, and in one case there was on several occasions a marked reduction of the pulse rate. The urine had remained normal in all cases. Thus far he had given thirty-one treatments. Doctor Hough then briefly reported three cases of paresis and one of cerebral syphilis in which he had employed this method of treatment. All of these patients were still under observation, and while he could make no statement as to the final results, he was convinced that it marked a distinct advance in the treatment of this hitherto almost invariably fatal disease. Judging from the effect that salvarsan had upon other similar spirochete diseases, especially yaws and other protozoan affections, and from the rapid advancement in chemotherapeutics as particularly indicated in the recent article by Ehrlich, he anticipated that in the near future the chemotherapy of syphilis would be so perfected as to prevent the development of the late nervous manifestations, which now showed such resistance to treatment.

Dr. H. S. Ogilvie, speaking for Dr. John A. Fordyce, who was detained at home by illness, reported the case of a man who was taken to the Riverdale Hospital on June 12, 1913. He was extremely loquacious and made numerous unreasonable demands and suggestions. The following night he became very noisy and fought his attendants violently. He was disoriented, and his delusions, both visual and auditory, were very pronounced. He was fearful lest his attendants should kill him, and insisted that his brother and other members of his family were plotting against him. He boasted of his vast wealth and power. On June 19th he was transferred to Sandford Hall at Flushing, L. I., where his condition remained unchanged for the following three weeks. At times he was quiet and would take a small quantity of food, but for the most part he was extremely noisy and at times violent, and it was necessary to keep him almost constantly under the influence of hyoscine and morphine. On July 16, 1913, the patient was given an intraspinous injection of thirty cubic centimetres of a forty per cent. solution of salvarsanized serum, after the method of Swift and Ellis, the serum being prepared from blood taken from another patient one hour after a full dose of salvarsan. No change in his condition was noted during the following ten days. During this period it was found necessary to catheterize him daily. He was practically confined to bed, as otherwise it was ex-
tremely difficult to control him. His delusions and grandiose ideas still persisted. His memory had apparently slightly improved and orientation was better. On July 26th, and again on August 4th, the intraspinous injection was repeated. Following these treatments he was quieter, took his food well and slept better. His grandiose ideas were less marked and he seemed to have a better insight into his condition. His delusions of persecution, however, persisted, although not so marked as before. On August 14th, about thirty minutes after an intraspinous injection, he had a mild convulsion. The nurse reported that his whole body suddenly became rigid and trembled for a few seconds, when he seemed to awaken with a start and looked about the room as though dazed. During the following week he steadily improved and sometimes it was almost impossible to detect any evidence of his psychosis. On August 22d he was given another intraspinous injection, which produced no reaction. The patient now seemed so much better that he was permitted to see his wife. He behaved well for the first fifteen or twenty minutes, but when the question of his leaving the sanatorium came up and he was told that he had better remain a few weeks longer he became very much excited and said that his family had no right to deprive him of his liberty. He agreed to return to the hospital, however, where he was now allowed to take long walks in the country and receive daily visits from his wife. He behaved well and showed but little evidence of his trouble. This was chiefly a tendency to be aggressive and sometimes unreasonable toward his attendants and physicians. On August 29th, he received another intraspinous injection. As there had not been much change in his condition during the two previous weeks, it was decided to treat him with serum from his own blood. On September 4th, he was given 0.45 gramme of salvarsan intravenously, and fifty minutes later about fifty cubic centimetres of blood was taken from the opposite arm. From this a forty per cent. serum was prepared, and on the following day he was treated intraspinously. He had no reaction from the salvarsan nor from the intraspinous treatment, and following this there was a very definite improvement in every way. The patient was brighter, he had a splendid insight into his condition, his grandiose ideas had practically entirely disappeared and he spoke kindly of his brother and his wife. He was so well that he was permitted to go home for two days, and upon his return to the hospital he seemed to be normal in every way. His last treatment was on September 11th, when he was again given salvarsan, followed by an intraspinous injection with a solution of his own serum.

Dr. H. A. Cotton, of Trenton, N. J., presented a young man of eighteen years who first came under his observation April 29, 1912, with the history of convulsions, the first attack in December, 1911, the second the following April, and after that occurring with greater frequency. He was then attending school, but had to give up his studies on account of increasing irritability and dullness. The patient had a specific history, and a lumbar puncture, made in April, 1912, gave a positive reaction. He received several doses of salvarsan, and in April, 1913, after a consultation with Doctor Swift at the Rockefeller Institute, the intraspinous treatment with salvarsanized serum was commenced. The injections were repeated every two weeks up to June 2nd, and the patient, who was now living on a farm, was still under Doctor Cotton's observation. The cytological findings were now practically negative, the patient had gained thirty pounds in weight and showed no mental abnormalities at the present time. He still had stiff pupils and an occasional convolution, but he was able to travel about by himself, and the improvement in his general condition had been very marked under this new method of treatment. In connection with this case, Doctor Cotton briefly reviewed the findings in eight additional cases of general paresis in which the intraspinous method of treatment had been employed by him. In two of these cases, that came to autopsy, salvarsan was found in the ventricular fluid, which seemed effectually to answer the query whether the remedy was carried to the brain after the intraspinous injection, or was limited to the cord. Doctor Cotton said that while these reports were only preliminary, the results obtained thus far had convinced him that this method would prove efficient, providing it was undertaken in the early stages of the disease. In his early cases, the clinical symptoms had undoubtedly improved, together with the biological findings. This did not hold good in the late cases. He had, however, seen no bad effects follow the treatment in the late cases; he knew of no contraindications to the method, and expected to continue to employ it, especially in the early cases. He regarded it as a step in the right direction, and said that in the intraspinous method of treatment we had something that promised well in general paresis. They all understood, of course, that there was no possibility of curing these patients in the end stage. Just how far a case of paresis could go before the treatment had lost its effect on the process they could not say. They should not expect to regenerate a paretic brain, but the results thus far obtained led to the hope that they might be able to arrest the process during the early stages of the disease. The extent of recovery would depend on the amount of destruction of the brain that had already taken place. At the Trenton State Hospital the treatment had been resorted to in nine cases, including the juvenile case shown tonight. In all of these, the pupils had remained stiff. The knee jerks had returned in one case. All the early cases had shown marked improvement, but in that connection they should take into consideration the normal proportion of remissions that were frequently seen in general paresis, as well as their own optimism in taking up a new method of treatment.

Dr. Burt Asper, of the Sheppard and Enoch Pratt Hospital at Towson, Md., said there was practically nothing to add to this excellent presentation of this subject. At the institution with which he was connected they had injected ten cases of general paresis and one case of tabes by the intraspinous method, and their results closely paralleled those reported by Doctor Hough and Doctor Cotton. At this hospital they were fortunate in having had two early cases. One was a stone cutter, thirty-nine years old, who gave a history of specific infection dating back twenty-one
years and in whom developed mental symptoms some two months before coming to the hospital. The case was unquestionably one of general paresis of the grandiose type, and the symptoms were typical. Following the first intraspinal injection the symptoms were aggravated, but after the second injection they moderated somewhat, and after the third one his mental condition cleared up entirely, although his physical signs remained unchanged. His memory defect had disappeared and he was permitted to return to his occupation, at which he was still engaged. Thus far he had shown no evidence of a relapse. He was still under observation and treatment. The second early case was that of a cigarmaker, forty-five years old, whose mental symptoms dated back six months. They were of the maniacal type and cleared up entirely under the intraspinal method of treatment. This patient was still under observation. Doctor Asper expressed the opinion that in the intraspinal injection of salvarsanized serum they had a very valuable method of treating general paresis—something which they had never had before.

Dr. Homer F. Swift, of the Rockefeller Institute, said that their experience with the treatment of general paresis by the intraspinal method was comparatively limited, and he would restrict himself to a few points in regard to the method. He was interested in the statement made by Doctor Cotton that after an intraspinal injection, the fluid taken from the ventricle of the patient was found to contain arsenic. This finding was in line with some work done in Dr. John Howland’s clinic in Baltimore, where phthalein was introduced by lumbar puncture into the subarachnoid space and two hours later fluid obtained from the ventricles was shown to contain phthalein—fifty per cent. of phthalein compared with one hundred per cent. in fluid obtained at the same time from lumbar puncture. In cases where the phthalein was introduced intravenously, however, there was no excretion into the fluid of either the ventricles or subarachnoid space. It was fair to assume, therefore, that arsenic or other drugs introduced into the spinal canal by means of lumbar puncture reached all points of the cerebrospinal system (as least the larger cavities) which were bathed by the cerebrospinal fluid. Uhlmann had shown that after intravenous injection arsenic was not present in the tissue of the nervous system in the same proportion as in other parenchymatous organs. Doctor Swift said that the experience with the direct introduction of neosalvarsan into the spinal canal had shown that severe, unpleasant symptoms followed the use of the drug in this way. Both from a practical and experimental standpoint, the direct introduction of salvarsan into the cerebrospinal fluid was inadvisable. Contrary to the experience of some of those who preceded him, no catheterization had been necessary after the introduction of salvarsanized serum into the spinal canal except where the patient had previously suffered from retention. In most of the cases the bladder symptoms had improved following intraspinal injections. Doctor Swift said that he wished to call attention to the value of the titration method in making the Wassermann test of the cerebrospinal fluid, and the importance of using a large quantity of the fluid. In making the test, they employed up to five volumes, compared with blood serum, and by using these larger quantities, the negative reactions became less numerous. The speaker also mentioned the value of making control tests, continuing either intraspinal or intravenous treatment until a negative reaction was obtained. In their own cases the improvement in the reaction usually went hand in hand with clinical improvement. In some of the cases the fluid had remained negative for a year and a half after cessation of treatment, and there had been no advance in the tabetic symptoms. They had found that the pleocytosis was the first to disappear, the Wassermann was more likely to disappear next, and, finally, the globulin excess. In the four patients with paresis or tabetoparesis the clinical improvement had not been very marked. One of the patients, however, was showing very distinct improvement. Patients with an initial, intensely strong Wassermann reaction in the cerebrospinal fluid usually required much more treatment than those with a weaker reaction. Of twenty-seven cases of tubers that were under treatment with the combined method, fifty per cent. showed an entirely negative Wassermann in the fluid; thirty per cent. required the largest quantity of fluid to show a reaction. If tubers and general paralysis were similar diseases involving different portions of the central nervous system, then the results obtained in tubers certainly offered an encouraging outlook in paresis.

Dr. H. LeBaron Peters, of Bridgeport, Conn., said he had at the present time six cases under treatment by the intraspinal injection method, of which none had received more than four treatments. Two of these were cases of general paresis, two of tubers and two of cerebrospinal syphilis. The two paretics had shown considerable improvement from the biological point of view, and in one of them, particularly, there was a marked clearing of the mental condition. Of the others it was too early to speak definitely. No untoward symptoms following the treatments were noted, except in the case of one of the tabetics. Here, however, there was for several hours after the treatments a marked exacerbation of lightning pains.

Dr. William M. Leszynsky said that it was not at all surprising that salvarsan should be found in the fluid in the lateral ventricles after injections into the spinal canal. During the epidemic of cerebrospinal meningitis several years ago, it was noted by the late Dr. H. P. Loomis that after argyrol was introduced into the spinal subarachnoid space, it was found at the autopsy distributed over the cerebral cortex.

Letters to the Editor.

PENNSYLVANIA’S INSANE ASYLUMS.

PHILADELPHIA, December 8, 1912.

To the Editors:

May I beg the favor of sufficient space in the Journal to say just a word or two on behalf of Pennsylvania’s insane asylums, the management of which is so severely arraigned in the editorial article appearing in your issue for October 4, 1912?

I beg leave to say that such a condition of affairs as therein described could not possibly exist in either the
BOOK REVIEWS.—INTERCLINICAL NOTES.

December 20, 1913.

The appearance of the eighth edition of this well known book demonstrates its popularity as a textbook for medical students. The present edition has eliminated much that was obsolete in earlier volumes and one can meet with considerable new matter and illustrations. In the chapters devoted to operative surgery a number of recent procedures have been introduced. The book has retained its previous size and form and confines itself chiefly to the wants of the student. It remains essentially a practical treatise intended to give the student the necessary information on the technic of bandaging, x-ray, antisepsis and antiseptic preparation for operation and operative surgery.

In addition, the subject of fractures and dislocations, particularly the use of the various splints, receives a brief consideration. The form will doubtless continue to be widely recommended as a textbook for students when taking up these important and practical subjects.

This epitome, like others of its kind, is supposed to give a bird’s-eye view of some particular branch of medicine, and the reader is expected to consult the detailed maps for further information. Unfortunately the great majority of students will content themselves with a very fleeting glance and trust that they will not go astray. For that reason I feel that this book is of much use to the inexperienced student, while the advanced student will wish something more extensive.

This epitome, like others of its kind, is supposed to give a bird’s-eye view of some particular branch of medicine, and the reader is expected to consult the detailed maps for further information. Unfortunately the great majority of students will content themselves with a very fleeting glance and trust that they will not go astray. For that reason I feel that this book is of much use to the inexperienced student, while the advanced student will wish something more extensive.

Book Reviews.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

This work represents a skillful choice of information taken from many authorities and combined in a systematic manner, so that it becomes an excellent manual for students and beginners in surgery. The text is unusually well written and the facts are presented in the most concise and clear manner. Originality is absent, but this in no way interferes with the usefulness of the volume as a textbook. All history, bibliography, and unnecessary details have been eliminated so as to make the book definite and practical.

There is some doubt as to the necessity of a new book of this sort, on account of the very excellent ones that have been written of late, notably by English authors, covering this field. At the same time this book will rank well above others inasmuch as he is not only well written but is successful both in manner and form. The form unfortunately is small and difficult to read, and the illustrations in general are poorly executed. This seems inexcusable at the present time when so much thought and work is being given to the perfection of print and elaboration of the illustrations. These comparatively minor defects, however, could be easily corrected in a subsequent edition. The author gives full credit to the various authors from whom he has taken his information and method of classification.

INTERCLINICAL NOTES.

It is rarely given to any layman to be received with hearty acclaim by a gathering of distinguished physicians and surgeons. Mr. Samuel Hopkins Adams, therefore, is entitled to congratulation on his enthusiastic reception accorded him when he appeared on the floor at the recent meeting of the Clinical Congress of Surgeons of North America in Chicago. The applause with which he was received showed that the medical profession appreciates the fact that he has done a great deal in exposing the fraudulent character of patent medicines and warning the public against them. Mr. Adams carries on the work in a recently published volume, The Health Master (Boston and New York, Houghton, Mifflin, & Co.)
For several weeks the Outlook has been delighting its readers with a handsome new makeup, which includes well chosen illustrations, and apparently gives more space for the typical woman's illustration of its editors and contributors. In the issue for December 6th, there is an ironical comparison between the attendance at the Fifth National Conservation Congress at Washington and that at the Baby Saving Congress in the same town. The impression prevails that any fool can raise a child, the ancient confusion of mind between begetting and training the offspring still persisting, the case of the former leading to general misapprehension of the difficulties of the latter. The Outlook also discusses the true mission of the milk station and the status of the milk bureau. There is a picture of the open air school for girls at Bryn Mawr and another of the strange looking fish that come from the depths of the sea; whereas we came, too, brethren, it is now some aeons since.

* * *

Wayside Experiences, by C. Elton Blanchard, M. D. (Physicians Drug News Company, Newark, N. J., $1.25 net), is a collection of tales and reminiscences which scarcely needs the apology the author makes for its publication in his preface, for it is interesting and by no means short. We should have thought Doctor Blanchard's experience would have known better than to offer as a raison d'être for a book the mere reality and sincerity of its contents. Nothing can excuse the lack of art in any work of art. There are some inaccuracies and inelegances in the book; "lady physician" is one of the latter and referring to Susan as a cognomen is inaccurate. Marvin was the cognomen of the woman in question. The style, however, is simple and unaffected. The stories are interesting, and our friends, after reading them, will easily find patients who will be thankful for an opportunity to be amused and instructed thereby.

* * *

Among the articles in the Popular Science Monthly for December, 1913, that the busy practitioner will probably read, with simultaneous regret that he has not time for all, are the sketch of Alfred Russell Wallace, by Dr. Henry Fairfield Osborn, and the second part of Alcohol from a Scientific Point of View, by Dr. J. Frank Daniel. We recommend highly the ironical and forceful article by Dr. P. H. Churchman, The Place of Study in the College Curriculum.

Meetings of Local Medical Societies.

MONDAY, DECEMBER 22d.—Medical Society of the County of New York.

TUESDAY, DECEMBER 23d.—New York Dermatological Society; New York Psychoanalytic Society; Metropolitan Medical Society of New York (annual); New Hospital for Women; City Rivers Medical Association; Physicians' Society; Valentine Mott Medical Society, New York; Washington Heights Medical Society, New York; Woman's Hospital Society, New York; Alumni Association of Seneck Hospital, Brooklyn; Rome Medical Society; Buffalo Academy of Medicine (Section in Pathology).

WEDNESDAY, DECEMBER 24th.—New York Academy of Medicine (Section in Laryngology and Rhinology); New York Surgical Society; Medical Union, Buffalo; New York Society on Rheumatism.

THURSDAY, DECEMBER 25th.—Bronx Medical Association; Hospital Graduates' Club, New York; New York Celtic Medical Society.

FRIDAY, DECEMBER 26th.—New York Academy of Medicine (Section in Public Health); Academy of Pathological Science; New York Society of German Physicians; Italian Medical Society of New York; New York Clinical Society; Manhattan Medical Society; Hospital Graduates' Club, Brooklyn; Audubon Medical Society.

SATURDAY, DECEMBER 27th.—West End Medical Society; New York Medical and Surgical Society; Harvard Medical Society; Lenox Medical and Surgical Society.

United States Army Intelligence:

Official list of changes in the officers and duties of officers serving in the Medical Department of the United States Army for the week ending December 14, 1913:

Billingslea, C. C., Captain, Medical Corps. Granted leave of absence for seven days. Eastman, William R., Major, Medical Corps. Relieved from further temporary duty in the Southern Department, to take effect and return to proper station, Fort Riley, Kansas. Ebert, R. G., Colonel, Medical Corps. Ordered to Fort George Wright to investigate matters relating to Major B. J. Edge, Jr., Medical Corps. Houser, Frederick H., Lieutenant, Medical Corps. Granted leave of absence for two months, effective at such time after the completion of his examination for promotion as his services can be spared by his commanding officer. Kramer, Floyd, Captain, Medical Corps. Granted leave of absence for two months.

Births, Marriages, and Deaths.

Bennett.—In Clearfield, Pa., on Saturday, November 20th, Dr. Ashley D. Bennett, aged seventy-seven years.

Cleveland.—In Canton, Pa., on Saturday, December 6th, Dr. J. E. Cleveland, aged eighty-four years.

Cornell.—In Copemish, Mich., on Tuesday, December 22d, Dr. Alexander S. Cornell, aged sixty-eight years.

Denver.—In Denver, Co., on December 16th, Dr. J. Walter E. K. Davis.

Elliott.—In Brooklyn, N. Y., on Friday, December 12th, Dr. Amos Henry Elliott, aged seventy-three years.

Farewell.—In Brooklyn, N. Y., on Thursday, December 11th, Dr. Norine F. Farewell, aged ninety-three years.

Hueston.—In Ypsilanti, Mich., on Saturday, December 6th, Dr. James Hueston, aged eighty-two years.

Huntington.—In Newport, Mass., on Tuesday, December 9th, Dr. Thomas Marshall Huntington, of Amesbury, aged fifty-five years.

Lathe.—In Boston, Mass., on Friday, December 5th, Dr. Leonora F. Lathe, aged seventy-nine years.

Layman.—In Philadelphia, Pa., on Saturday, December 6th, Dr. Alfred Layman, aged seventy years.

Manahan.—In Brookline, Mass., on Sunday, December 7th, Dr. Margaret M. Manahan.

Nelson.—In Norwich, Conn., on Saturday, December 6th, Dr. Abiel W. Nelson, aged seventy-eight years.

Pulliam.—In Tolono, Ill., on Sunday, November 30th, Dr. Willia T. Pulliam, aged eighty-one years.

Rogers.—In Newton, Iowa, on Thursday, December 4th, Dr. Lee O. Rogers, aged seventy-five years.

Sager.—In Rockford, Ill., on Tuesday, December 2d, Dr. Rockwood Sager, aged fifty-seven years.

Stratton.—In Tiffin, Ohio, on Thursday, December 11th, Dr. John W. Stratton, aged sixty-eight years.

Street.—In New Bern, N. C., on Monday, December 1st, Dr. Nathaniel Heath Street, aged fifty-six years.

Von Klein.—In Chicago, on Friday, December 12th, Dr. Carl H. von Klein, aged seventy-one years.

Ward.—In St. Johnsbury, Vt., on Monday, December 8th, Dr. R. C. Ward, aged seventy-five years.

Wishard.—In Indianapolis, Ind., on Tuesday, December 9th, Dr. Henry Wishard, aged ninety-seven years.

Ward.—In Springfield, Mass., on Sunday, December 7th, Dr. Fitzwilliam S. Worcester, aged sixty-two years.
Original Communications.

THE CANCER RESEARCH HOSPITAL.*

By James Ewing, M. D.,
New York.

In the year 1913, New York State opens a hospital for cancer research. The event is significant. When a State legislature commits itself to clinical cancer research and devotes public funds to this purpose, it establishes important precedents.

It means that enlightened public sentiment in this community is not satisfied with maintaining homes for incurables and that the study of cancer in the human being is worth while, and a legitimate State function. One can hardly expect an event of this character to attract great public attention. The public mind is chiefly interested in sociological experiments on a large scale, the larger the scale the better; to determine how a man shall get along with his neighbor, and how the wealth of the land shall be distributed.

The lust and worry about money may be a very important economic question, but its solution does not tell essentially for the permanent betterment of mankind. Humanity advances chiefly through enlarged control of its physical environment. This type of progress is dependent upon the sciences.

The world's real work is being done by a relatively small army of physicists, chemists, and biologists, whose average wage is little larger than that of the bricklayer. They have no trades unions, no cyclic demands for larger pay, and their fortunes will not generally be reached by an income tax.

The public at large is an unsuspecting and innocent beneficiary of the slowly gathered fruits of this labor and receives only a belated newspaper notice of the sensational phases of scientific progress. It is hardly to be expected that the average man in the treadmill of American life should busy himself with the interests of science, but it may not be amiss to refer to this aspect of the socialistic movement of our times.

Possibly those in control of the forces which design to take over a large portion of American fortunes propose also to assume the responsibilities heretofore carried by these fortunes. Practically all the support of American science has come from men of large means, but one does not hear of any political platform which clearly proposes to maintain and enlarge the immense philanthropies now voluntarily supported by the rich. Indeed, one may gravely question whether the general intelligence of governing bodies in America is equal to this task.

In fact, the public utterances of many men in high places indicate a firm resolve to readjust the wealth of the land, but little concern as to how they are going to spend the money.

American science has much at stake just now, and it may become necessary urgently to push its claims into public notice to avoid a long period of repression. Especially is it to be feared, when the support of science becomes a governmental function, that the finer appreciation of the peculiar needs of medical research may not be felt by the successful political leader, and that the optimism which is willing to risk large resources on faint possibilities may not appeal to political bodies at all.

Under these circumstances the action of the State of New York in establishing new relations to an important department of medical science, assumes a significance not realized by the man in the street. Yet as I interpret the function of to-day's ceremony in Buffalo, it is just to do what the man in the street will not do, pause to consider the meaning of a decision which commits the State of New York to cancer research in the clinic.

It is no reflection upon the intelligence of our legislature to suggest that this movement did not arise within its ranks. The layman's impression of the cancer is of something very indefinite, very portentous, quite hopeless, a disease which always affects some one else than himself, about which he carries no immediate interest or responsibility. This point of view does not originate any activity in the fight against cancer.

Neither can it be supposed that the medical profession with its larger acquaintance with the disease rose up and demanded that the State enter upon this field of work for the public health. The average physician is a confirmed pessimist on the cancer question, and probably the profession as a whole feels that the community has done its full duty in providing routine surgical skill for the early cases, and asylums where the advanced stages of the disease can run their course under bandages and morphine anesthesia.

No, the impetus for this movement must have come from some specially enlightened and aggressive source, from some man or group of men who are fully alive to the real needs of the cancer situation, both from the humanitarian and from the scientific sides.

The city of Buffalo may well be congratulated upon the possession of such leaders in medicine,
for the scientific pursuit of a large problem and is especially valuable in revealing the extensive equipment and expert organization which is required for the successful study of many biological problems.

Not the least significant phase of this work was the stirring of the United States Government to its support. Finally, to complete this record of qualifications the institute is known for its consistent contributions on the serology of tumors, on many chemical questions of importance, and in the testing of reputed therapeutic agents as well as the elaboration of original ideas in experimental therapy. Through these highly profitable years spent in experimental studies, the institute has maintained an attitude of dignified optimism regarding its own work and the general progress of cancer research. It has not overexploited itself, nor overestimated the importance of its own work, nor assumed for itself, much less openly claimed for itself, any specific inspiration or apostolic authority.

On the contrary, as the most active influence in the foundation of the American Association for Cancer Research, as a joint originator and notable supporter of the International Association, and as a cordial friend and helper of many colleagues in this country and abroad, the Buffalo institute stands in an enviable and unassailable position. To such an institution now comes the responsibility of conducting intensive research upon cancer in the human patient. The hospital is open; what is to be done with it?

The experiment of extending the activities of laboratory workers to cancer in the human subject and of gathering for this purpose under one roof a considerable number of patients mostly in the condition called hopeless, is an experiment, but not entirely a new one. At least three American institutions and several abroad are already organized in this way. The uncertain feature of the plan concerns the possibility of maintaining a desirable mental atmosphere about an institution peopled largely by all too obvious victims of a dread disease.

This difficulty has stood in the way of the establishment of cancer homes, and some good surgeons feel that it is an insuperable objection to the cancer research hospital. Others, mostly lay persons whom we need not stop to classify, gravely fear that the patients in such a place will serve merely as subjects for experimentation, with very deleterious effects upon the morals of the experimenters. Yet the brief experience of existing cancer research hospitals is distinctly to the effect that a reasonable optimism may be maintained among the patients and personnel.

Write the word "hope," meaning hope only of definite palliation, over the door of a home for cancer incurables and you convert that home into a live cancer research hospital. You can fill it several times over with eager patients. Even without the promise of more than routine medical and surgical care, there is no field of hospital work so inadequately provided as are the needs of the inoperable cancer patient. The physical suffering entailed by cancer is not a part of our topic, but the attention of philanthropists may well be called to the urgency of this need beside which most other charities appear dwarfed. But it is not for the mitigation of
suffering by the better application of known methods that the research hospital is primarily intended. It is for the much larger ambition of adding to our knowledge of the nature and control of the disease by its more elaborate and careful study in the human subject.

About ten years ago a notable investigator, discussing the new observations on artificial immunity to cancer in lower animals, declared that the outer breastworks had been stormed and it was only a question of time when the inner citadel would be captured and cancer become a solved problem. Perhaps because of weary desertions from the ranks, the capture of the citadel has been delayed. In fact, I think it must be candidly admitted that the results of the modern era of experimental cancer research from the standpoint of the human patient, have been disappointing. I hasten to add that this point of view may not be a legitimate one from which to judge the results of this era. Workers in the most obscure problem of medical biology resent the question, "How many cases of cancer have you cured?" There is no obligation resting upon cancer research to arrest the course of a naturally fatal disease, any more than the chemist must justify himself by making diamonds out of charcoal. It cannot be too strongly urged that the value of contemporary results in the study of cancer should not be estimated from the therapeutic side. One must be prepared to face the contingency that the problem of advanced inoperable cancer may always remain a therapeutic impossibility, and there is strong reason for believing that it will so remain during our present era.

Many believe that exclusive attention to the direct attack upon cancer in man stands in the way of necessary fundamental progress, and that we are not ready for the therapeutics of cancer. While fully assenting to the general validity of these objections, I cannot help feeling that modern cancer research owes something to its day and generation, and I have been impressed by the fact that the very significant advances of the past decade in some departments of research have brought very little relief to the cancer victim.

It is highly interesting and theoretically important that many cancers in rats and mice spontaneously regress, but we already know this to be true of human cancers and that the event is very much less frequent in man than in lower animals. Perhaps some day we may learn from the lower animal why this regression occurs, and be able to facilitate the process in man. The modern progress stops short of this goal.

It is very encouraging to be able to arrest tumors in animals by blood transfusion, by various trauma, by strangling the bloodvessels with epinephrine, by poisoning the animal by various toxic agents, by high temperatures, by injections of colloidals metals, even by simple changes in diet; or by complex synthetic compounds labelled "chemotherapeutic" agents, and by many other procedures, but therapeutic tests on a vast scale, in many countries, return the verdict that these methods are ineffective in man. Serological studies have revealed many subtle changes in the blood of organisms suffering from cancer, but with the possible exception of Freud's observations that cancer blood has lost the normal capacity to dissolve cancer cells, this work has not elucidated the nature of cancer predisposition, nor enriched our practical diagnostic measures, nor opened the way for constitutional treatment of the disease.

It is quite confusing to learn that certain tumors or tumorlike processes in chickens can be transmitted by an agent filterable through porcelain, but this is the only department of chicken pathology that has been carefully investigated so that one hesitates to apply this principle to any process in man; its interpretation in the chicken is difficult; and it may very well be that this problem, somewhat artificially created, in spite of being very ably pursued, may lead nowhere in the etiology of human tumors.

Likewise, the discovery of an epidemic of cancer of the stomach in rats and the brilliant demonstration that this disease is connected with a nematode worm found in a limited circle of cockroaches which enjoyed the rich diet of a Copenhagen sugar factory, furnishes a model of scientific acumen and finished research, but there is not the slightest indication that gastric cancer in man has any parallel etiological relations.

While a very high value must be placed upon these and other notable results of the study of tumors in lower animals, does it not appear, on the whole, that this field of work is somewhat distantly removed from the real problems which animate cancer research? The variations in biological processes are almost infinite. The direct attack upon cancer has proved ineffective, but it is not necessary to aim the guns as far away as possible in the hope of opening up effective side paths of approach. There is a growing conviction that to know cancer in man one must study the disease more carefully in the human subject.

In the past few years the development of facilities for this type of research has progressed with great rapidity. It is worth noting that at least ten special institutions of this sort have come into existence in the past few years, indicating a very strong current toward human cancer research as against the purely experimental field.

The problems presented in the cancer research hospital are so numerous and conspicuous that their contemplation at once reveals that this is the broadest and the most profitable of all departments of the subject. Here is the place for the study of etiology in which clinical observation has already furnished our most important knowledge.

A young surgeon, in discussing a communication on precancerous conditions of the breast, recently asserted that a disease is either cancer or not cancer. Quite the contrary; a pathological condition may be neither the one nor the other. It may be in the process of becoming cancer, and this process takes time, sometimes years, and is attended by certain rather definite morphological changes easily detected by the microscope and often recognizable by the naked eye, as well as by very important changes in physiology. It is a highly important fact that these precancerous conditions are usually remediable by the knife, or by less violent measures.

The great majority of cancers, according to Billroth, all of them in many regions, are preceded by
such preliminary changes. Much is known, but more remains to be learned about precancerous conditions. They are of very general clinical interest, but the cancer hospital should contribute an important share in the more careful study of these conditions and in the spread of the knowledge thus obtained.

The special etiology of tumors varies with each particular variety and constitutes a large chapter of our knowledge of cancer. It presents one of the most comprehensive fields of clinical research for which an extensive acquaintance with the literature of the disease and with general medicine is essential. I sometimes think that those who frequently emphasize and deplore the paucity of information about the nature of the cancer process would do better to familiarize themselves with what is actually known about the very numerous factors which condition the development of tumors.

We may never know just why cancer cells grow lawlessly, but we can elucidate a vast number of conditions under which they are observed to do so and perhaps remedy the conditions. The influence of racial, local, and personal habits upon the nutrition and functions of different organs, the traces of heredity, the evidence and nature of local tissue and general constitutional predisposition, the influence of chronic infection, of trauma, and many other matters enter into the etiology of tumors, and should be pursued in a cancer hospital by observation, analysis, and experiment, by clinician, chemist, and pathologist.

The cancer hospital is no place for the immature and indolent mind, either in the wards or on the administrative staff. Unstable emotions and sentimentality of every other kind are out of place in its neighborhood. The spectator of humanity bowing before the unhindered progress of a disease which tends almost inevitably to a fatal issue, often with much physical pain, can be calmly viewed only in the light of science. In this light there is value in every observation steadfastly pursued to the end.

The natural history of cancer is far from a finished story and has never been adequately written. The medical profession is in the habit of regarding it as a single disease varying chiefly in location and prognosis. This view is as profound as the ancient impression of inflammation, which grouped tuberculosis, syphilis, and pyogenic infections, as well as many tumors, in one category. But there is no more justification in identifying embryonal cancer of the testis with cancer of the breast or epithelioma of the lip, or traumatic sarcoma of the long bones than for confounding lobar pneumonia with typhoid fever. The tumors mentioned are related only as forms of neoplasia, the infectious diseases only as inflammations.

The etiology, symptoms, clinical course, and indications for treatment, which constitute the specific quality of clinical entities are in many cancers quite different. Not until we come to recognize the individual character of different tumors, benign and malignant, can we comprehend their true significance.

The cancer hospital offers conditions where the natural history of tumors can be observed and recorded in all its phases, and where our knowledge of this vast and comparatively neglected department of medicine can be greatly amplified. For this purpose, a well organized department of pathology is essential, every type of patient in any stage should be admitted, and the public should be educated to the necessity of post mortem study of every fatal case.

As a factor in medical education every one must see the immense influence which the cancer hospital is capable of exerting. I would recall the declaration of the American Association for Cancer Research, that the knowledge of the early symptoms, diagnosis, course, and treatment of cancer is very inadequately taught, even in the best medical schools. It cannot be adequately presented as a clinical study because the hospitals shun the advanced cancer patient. The inefficiency of our present methods of diagnosis is shown by the statistics of the best Berlin hospitals, which prove that twenty per cent., even of fatal cases, come to autopsy unrecognized. The microscopic diagnosis of tumors is one of the most difficult of laboratory specialties, requiring many years of experience, and often much careful and competent consideration, but much of this work is done by laboratory tyros, chemists, and drug stores. Yet when the facilities for acquiring this knowledge are so limited, one should not blame the surgeon too severely for his amazing confidence in the amateur and the fakir.

The grave defects in the knowledge of the average practitioner of primary facts about the early diagnosis and treatment of cancer have been revealed by many investigations of this subject conducted by clinicians themselves with the conclusion that the chief hope of an immediate reduction in the mortality from cancer lies in its earlier recognition. For this end the public should doubtless be made acquainted with the early symptoms of cancer, but first of all the competency of physicians must be assured.

The cancer hospital in connection with a university can do more than any other institution to provide material for the educational movement. It should collect a gross and microscopical museum, train expert diagnosticians, and open its wards freely to students.

Under such conditions much new and important information concerning the nature, etiology, histogenesis, and prognosis of tumors, and the relation and classification of neoplasms can be acquired. To the experimentalist all this is dull routine, mere skirmishing and sharpshooting, and will never lead to the grand upheaval with the storming of the citadel revealing the great secret of cancer. Yet it should be recalled that the great bulk of our knowledge of the disease has been acquired by just such methods of painful and persistent observation and analysis of apparently routine phenomena. Moreover, the results of experimental study in all fields must eventually come before the bar of just such scrutiny. Total of clinical and pathological experience with the disease and there be judged as to their validity.

Personally, I find so much of interest in the study of etiology, histogenesis, prognosis, and classification of human tumor material, that I have never been able fully to indulge a passion for artificially
created problems, and I have an impression that this sort of work tells effectively, although indirectly, in reducing the mortality from cancer. One must obviously supplement the old fashioned methods of study by serology and chemistry with experts specially interested in cancer problems. In these fields human material appears to be essential and for this end alone the cancer hospital would justify itself. Very important problems in both these departments are beginning to define themselves.

The chemical study of tumors and of the affected organism is still in its infancy. In fact it seems to enjoy recurring periods of infancy. It was highly in vogue in Virchow's time. So far as I can learn there are only two studies of the sugar content of the blood in cancer, one about 1860, reporting an increase, the other in 1910, recording a decrease or variations in this substance. Among many other problems, one awaits the results of modern chemistry as a necessary basis for the ambitious science of chemotherapy of cancer into which some would boldly venture without such light.

Serology also has made a conspicuous entry into cancer research, and will doubtless prove an essential instrument in elucidating many subtle changes in cancer processes. Both these sciences should be adequately represented in a cancer hospital.

Therapeutic studies are bound to claim a large share in the activities of a cancer research hospital. In fact a hasty tour through such institutions in England and the Continent might suggest that this is their only real interest. It would at least convince the visitor that the partial success of the palliative treatment of inoperable cancer fully justifies all the support these institutions have received. To the harsh critic, the treatment of inoperable cancer is nothing more than a form of euthanasia, and such as a rule it proves to be. Yet the palliative treatment of these patients is a worthy service, demanding far more patience and skill than are involved in most routine functions of the physician. It is an intellectual rather than a mechanical occupation, and when it is well done calls for the skill of an artist.

I suppose that when Czerny began to take an active interest in the palliative treatment of cancer, it was by some regarded as the beginning of the end of his career. But I recall that it was only in his old age that Abraham was taken up into the mountain and had his eyes opened to the promised land. Not a few distinguished surgeons have been willing to devote minute attention to this subject, which calls for much surgical skill and experience and for a knowledge of many adjuvants to surgery. Of the very numerous devices which are shown to retard the progress of cancer I do not propose to speak, but merely mention that this field should be developed to the highest possible point which its costly nature permits.

With rare exceptions, I think the principle should be followed of prolonging life to the limit, not only because life with hope or consecutive activity is generally worth while, but because surprising improvement may be observed, and there are on record very puzzling cases of apparent recovery from the last stages of cancer.

There is also recorded a series of malignant tumors with very prolonged course occasioned by periods of quiescence under elaborate palliative treatment, and there is little doubt that this frequent tendency of the disease is not always encouraged to assert itself. I regard these cases of spontaneous partial arrest of cancer as highly important objects of study, illustrating phases of cancer immunity. None of them, so far as I know, has ever been fully studied from the serological and chemical sides. It was with such a case that Hodenpyly made his interesting observations, showing the un doubted presence for a time of a curative agent in the chylous ascitic fluid of breast cancer.

Successful palliation is not, however, the sole therapeutic ambition of a cancer hospital. The numerous methods which have proved capable of retarding or eradicating experimental tumors in animals naturally rouse the hope that some one of them may be found effective in man. Thus far none of these biological methods has had any significant influence over generalized or advanced human cancer, although isolated paradoxical results are credited to many, while not a few give temporary mitigation of symptoms. In this situation it is difficult to avoid a form of quackery in clinging to a method whose influence is uncertain. Yet in a cancer hospital, where the financial element is eliminated, any method with a sound theoretical basis deserves a thorough test.

An enormous labor is now being expended in investigations of this class, but it must be seriously questioned if the field is ripe for any harvest from the vaccines, sera, metals, ferments, and complex chemotropic agents lately employed on an extensive scale. These agencies ignore every element of the disease except the cancer cell, they rest on an assumption that all cancer processes are essentially alike, and they indulge the hope that some shadowy property of a chemical body, diluted in the blood stream, may somehow arrest the momentum of a whole series of a headlong vicious process in cells and organs. I have often wondered if some of these agents might not be able to control the early stages of tumors, but against advanced or generalized carcinosis it seems a vain hope to set up any circulating material so far devised.

Yet for localized but inoperable cancer there has recently come renewed hope and from partially discredited sources. Radium and its allies have made a steadily enlarging field for themselves in the treatment of localized and inoperable tumors. It has long been known that sufficient exposure to radioactivity kills cancer cells while sparing normal tissues, and it has remained a question of the technic of application how far this action could be employed for the control of cancer. So long as the use of radium was limited to superficial growths, just as well removed by the knife, it was regarded as an interesting and expensive toy, and when not a few aggravations of the disease were charged up against the careless or inadequate application, it assumed the character of a dangerous toy. No such atmosphere surrounds the reputation of radium to-day.
Every year has brought improvements in the methods of application, in the quantities available for use, in accuracy of dose, and in the observation of effects.

It has been demonstrated that radium is the best method of treatment of certain superficial and some deeper tumors which may also be removed by the knife, and that in a few conditions, deforming operations not certainly successful may well be avoided by its use. Much yet remains to be learned of the physics of radium and its products and of allied substances. Well equipped physical institutes in Paris, Birmingham, and Vienna are fast supplying this information, which will doubtless prove an important control in the medical application of radium.

The x-ray treatment of cancer has made substantial progress during the past year. Here again it has been a question of the technic of application, since the destructive action of x-rays upon cancer cells has long been recognized. By the repeated and prolonged application of filtered rays it has been possible to render many inoperable tumors accessible to the knife and in some instances completely to eradicate extensive although comparatively superficial growths which were formerly regarded as far beyond the reach of this or any other agent.

Thus the field of radium and x-ray as curative agents in cancer is rapidly widening, and the results already obtained assure for the cancer hospital a definite field of successful therapeutics of inoperable and borderline cases. Likewise the capacity of these agents as palliatives is correspondingly increased, so that by systematic employment of physical therapy, the melancholy aspect of the chronic cancer ward may be greatly mitigated.

The possession of an effective supply of radium, a fully equipped light department, and competent experts capable of breaking new ground, supported if possible by a trained physicist, are quite essential parts of the organization of a cancer hospital. While the ultimate results of the new methods of physical therapy are not yet known, and the real problem of the constitutional treatment of general-ized cancer still remains untouched, there is no doubt that very important new weapons have been made available for the fight against cancer.

From the consideration of these various functions of the modern cancer research hospital, I think that it must be evident that such an institution not only can justify its existence, but fills a very urgent need without which the progress of cancer research would be handicapped, and much relief that might easily be extended to cancer victims would be unavailable. Nor is there any doubt that the function of supporting such an institution is properly exercised by the State, which support should be continuous and liberal.

I have to confess that the plans of such a hospital, as they appear to me, do not contemplate the early subjugation of cancer, but look rather to the slow and painful attack upon a great number of problems which present in this broad field.

Personally, I do not look for any startling advances or sensational discoveries, either in the etiology or therapeutics of cancer. I do not think the citadel will ever be stormed. It seems much more likely that a steady reduction in the mortality from cancer will come chiefly from a large number of separate factors, of which the most significant appear to be increased control of the conditions leading to cancer, more general recognition of the preliminary stages of the disease, and earlier diagnosis and treatment of the established disease.

If there is any wisdom in this forecast, which I believe embodies the views of many workers in cancer research, then a prime importance attaches to all the various activities of a cancer hospital. Through the steady growth of our knowledge of every phase of neoplastic disease, and not by a single grand denouement by some inspired medical genius, will the problems of cancer meet their solution in due time. That the cancer process will ultimately yield before this steady advance of knowledge is, I believe, a legitimate conclusion. A tissue infiltrated by cancer is not wholly beyond repair. We need only recall the series of cases in which established cancer has spontaneously disappeared, leaving the affected tissues cicatrized but in a functioning condition. In the same way bulky gunmas disappear, leaving only moderate scarring.

In Mackay's well-known case there was probably extensive absorption of carcinomatous tissue and astonishing improvement in general health. Thus Nature occasionally heals the cancerous lesion, showing that such a result is well within the range of physiological possibility. That Nature's secret may be discovered or that the same result may be accomplished by other means, is a reasonable assumption. Already there are hints regarding the nature of certain agents that may eventually prove effective.

The deadly x-ray may be made to penetrate the deepest tissues, even the bone marrow, and radium may be sent circulating to the farthest corner of the body. It may be possible to intensify and localize the action of these physical agents. From the biological side we know that cancer tissue is in some respects specific and excites in the body the formation of specific antagonistic substances. Abderhalden has shown that these antagonistic ferments appear in probably every case of cancer and often in the early stages. Perhaps with early sero-diagnosis one may be able to intensify the protective processes in the body and arrest the disease in its incipient by following Nature's own devices. Again, the specificity of cancer tissue calls for a peculiar chemical composition or physical state with peculiar chemical affinities. Hence the ultimate basis of chemotherapy is well founded, and the search for effective agents in this field may some day be successful.

I would not attempt to predict in what direction the therapeutic labors of cancer research will prove most effective, but merely assert that its labors will not be in vain. The conception of cancer as a curable disease may well inspire an optimistic spirit in all who are engaged in its study.

The new institution formally opening to-day is the logical outgrowth of the optimism which led to the founding of the original Gratwick laboratory; it represents the larger scope of modern cancer research; it is destined to add much to our knowledge.
of human cancer, whether it makes sensational discoveries or not; it expresses the determination of discerning men to provide the State of New York with an institution fully equipped for its great purpose; it is a notable monument to the State of New York and the city of Buffalo; and it begins its career with the unqualified endorsement of medical science.

ILEOCOLITIS WITH MENINGEAL SYMPTOMS.

By A. L. GOODMAN, M. D.,
New York,
Visiting Physician to the A. Jacobi Department for Children,
German Hospital, New York City.

In preparing this paper on ileocolitis with meningeal symptoms, I wish to draw a sharp differentiation between those cases of meningeal inflammation in which bacteria are found in the spinal fluid and those in which, after repeated examinations, no organisms are demonstrable.

The acute intestinal infections are frequently referable to artificial feeding—fermentation of the milk being especially responsible. Thus a number of microbial species, as well as their toxins, are brought in contact with the young organism. The strong reaction to the infection in the digestive tract on the part of the child manifests itself promptly in a very complicated series of symptoms. Besides the various forms, of which diarrhea is a constant feature, a form of intestinal intoxication, with constipation, and accompanied by symptoms of pseudo-meningitis, has also been described. Any form of enteritis may give rise to cerebral symptoms. Genuine cholera infantum, however, does not cause meningitic disturbances, because, as a rule, the patient rapidly becomes comatose, and the nervous system has no time to react in the form of excitement. Convulsions in the course of enterocolitis are sometimes observed, and these cases must be differentiated from those forms of intestinal infection occurring in epileptics.

In 1894, Dupré, at the congress held in Lyons, defined meningismus as follows: “The features of meningismus, more characteristic by their association and their sequence, than by their character and nature, are the signs of general and local excitement of the cerebral cortex, followed by depression; these are added headache, vomiting, or constipation, with temperature variations, which, on account of their inconstancy and irregularity, represent the most important feature of the symptom complex. The scope of the temperature variations is governed by the cause of the meningismus.” Autopsies and bacterial examinations gave negative findings in certain cases where the diagnosis of meningitis had been made. This is explained by the action of microbial toxins of the intestine upon a prepared soil. An autointoxication of this kind is analogous to the same disturbances caused by alcohol, strychnine, or other poisons. Personally, I can explain these cases of meningismus only as attenuated forms of meningitis due to bacterial toxins. These toxins must be assumed as acting in some manner on the membrane, producing a certain degree of congestion. This action is possibly of a chemotoxic nature.

Oppenheim, in his Lehrbuch der Nervenkrankheiten, states that in children who are weakened by gastrointestinal catarrh some of the symptoms of meningitis are observed, such as somnolence, convulsions, trismus, etc. But the conditions which are designated as hydroencephaloid are characterized by the absence of fever, local symptoms, and involvement of the optic nerves. Moreover, the diagnosis can be established on the basis of the etiology, the size of fontanelles, and the associated phenomena.

Gastrointestinal autointoxication in children may give rise to conditions very closely approximating the picture of meningitis. The gastric symptoms, the indicanuria, the prompt effect of intestinal evacuation, permit the differentiation of these cases from meningitis. Lumbar puncture may also assist in the differential diagnosis.

According to Mülle, in his excellent thesis, the explanation of these pathological disturbances is found in the microbial flora of the digestive tract. The bacterial species which exist in the intestine of the child are somewhat variable and, according to the findings of Lesage and Thierulin, in the normal stools of nursing infants include large numbers of common Bacillus coli, which is normal—meaning harmless—in the ordinary proportion. Associated with it, but in smaller quantities, are found the following: Bacillus mensentericus vulgatus, Bacillus lacticus, some liquefying and nonliquefying micrococci, Streptococcus varieties, Bacillus fluorescens liquefaciens, and Bacillus fluorescens putidus nonliquefaciens, gram positive and gram negative.

Some other microorganisms are noted in the course of an acute gastrointestinal infection, such as Bacillus pyocyanes, isolated or associated with Bacterium coli commune. Association results in increased virulence, which produces a hypertoxicity of their soluble products. When these toxic infectious agents become distributed in the organism and find a favorable soil for their action, meningeal complications may result.

There are no specific microbes to explain the genesis of common gastroenteric infections. All the microbes which have been held responsible in this respect may be found in the stools of healthy infants. Aside from Bacillus coli and Bacillus lactis, which are always present, Streptococcus pyocyanes (peptonizing bacteria), and staphyloococi may be found as accidental contaminations in normal stools. The part played by Bacillus coli is a matter of controversy; while some regard it as the chief agent of infantile diarrhea, others deny its influence altogether. The action of streptococci has been demonstrated by Escherich and his school. Two varieties were found—Streptococcus brevis and Streptococcus gravis. Marfan isolated streptococcus eight times, four times in pure culture and four times in association with Bacillus coli.

Case. On April 18th, E. W., aged five years, male, was admitted to the A. Jacobi ward for children, of the German Hospital. Five days before admission, the child had begun to vomit, had numerous green stools, with slight traces of blood and mucus. No history of an indiscretion in diet could be obtained from the parents.

Examination on admission: A poorly nourished, anemic, neurotic looking child; no skin eruption. Eyes reacted to
GOODMAN: IECOLITIS WITH MENINGEAL SYMPTOMS.

light. Mouth: Teeth in poor condition; tongue slightly coated, papilla prominent and red; tonsils markedly retracted and not inflamed; crypts clear; pharynx covered with thick mucus. Chest expansion fair; respiration 28. Heart: With normal limits, sounds clear, no murmurs. Lungs negative. Abdomen scaphoid; soft and tender; no masses felt. Liver dullness from fourth intercostal space to costal margin in mideclavicular line; edge felt. Spleen not palpable. Rectal examination negative.

During the day in the hospital, the patient's temperature remained at about 99.4° F. He had a few loose stools, the laboratory reports on which were as follows: Brown and green, streaked with blood; some of the stools contained small amounts of mucus. When the stools were examined microscopically, there were numerous white blood cells, strings of mucus, many red blood cells. Amorphous particles stained yellow and green. No connective tissue or masses of epithelial cells seen. No ova. The blood examination showed 21,000 white blood cells; polymorphonuclears, 78 per cent.; lymphocytes, 20 per cent.

Because the boy had been so thoroughly purged before admission, and because of his extremely weak condition, he was given a Murphy saline of 500 c.c. The diet consisted of barley water, tea, and chicken broth, milk being eliminated. Medication consisted of small doses of subgallate of bismuth and peptic

At ten o'clock at night, on the day of his admission, the boy vomited a small amount of light yellow fluid. The second day, the temperature rose to 101.8° F, preceded by a slight vomiting spell; the green stools continued, and small amounts of blood and mucus were contained therein. Toward evening, the temperature fell to 99° F. Without any urinary symptoms, the urine examination, albumin, but large quantities of indican were present. On the third day, the temperature remained around 99° F., but the patient became apathetic, refused nourishment, and slept mostly all day. He gave the impression of being a very weak child. The blood and urine examination was negative.

The impression was made that the meningeal symptoms were negative. The following day the apathy was increased. At 9 a.m. he had a slight convulsion, lasting four minutes; at 1:45 p.m., another convulsion, also lasting four minutes, and at 5:15 p.m., a third convulsion, lasting two minutes. The convulsions involved the entire right side of the body, including the face. This was followed by a complete paralysis of the right arm and leg. At this time, about 10 a.m., there were definite signs of meningitis; the stiff neck, the Kernig sign, and Babinski's sign. The test for positive Babinski was made on making afternoon rounds. I was amazed to find that the paralysis had entirely disappeared, and the patient was able to move both of his arms and legs. On the following day, the patient was able to sit up, one at 2 p.m., and one at 4 p.m., each lasting five minutes, again followed by paralysis, at first flaccid, then becoming spastic, and also involving the left leg. This paralysis, or apparent paralysis, lasted until the following noon, when the patient was again able to move all his extremities. Electrical examination showed normal reactions; the urine still contained traces of indican. High enemata were given daily. On the fourth and fifth days, when the convulsions appeared, spinal puncture was reported. The first puncture showed a pressure of 110 mm.; clear; specific gravity, 1.004; no albumin; reducing substance uncertain; butyric acid test negative. The second report was also negative. The spinal fluid injected into guineapigs showed no reaction. Widal, von Pirquet, and Wassermann reactions were negative. To the spinal fluid, and peptic medication, hexamethylenamine in doses of two grains three times a day was added. After the convulsions, on the sixth day of the disease, the boy gradually improved and showed a remarkable recovery. The green and bloody stools ceased, the indican disappeared from the urine, and the boy was able to be up and about two weeks later, without any functional or organic disorder. Reflexes were normal. Electrical reactions normal.

The peculiar features of this case were the moderate temperature, the irregular, slow pulse, the rapidly disappearing paralyses, and the complete recovery.

In reviewing the literature, one is amazed at the enormous number of cases of meningial irritation occurring in the course of infectious diseases, such as typhoid, scarlet, and other febrile conditions. I would refer those of you who are interested in this subject to the excellent work of Cole and McCallum, in the Jons Hopkins Hospital Reports. In our case, however, we had to deal not with bacteria, but with their toxins. Bouquet, in Gazette des hôpitaux, acknowledges the existence of a pseudo-meningitis as occurring with intestinal disorders. It seems reasonable that these conditions may, reflexly, give rise to symptoms suggestive of meningitis. It should also be kept in mind that these various conditions are frequently combined with intestinal disturbances capable of generating toxins, and acting upon the nervous centres in the same way as microbic poisons in the course of infections. Even transitory digestive disturbances in children are known to be very often accompanied by nervous symptoms. Many of these patients are nursing infants, who, in the course of intestinal infection, present rigidity at the nape of the neck and the lower limbs, with slight tension of the fontanelles. Lumbar puncture may show slight hypertension. In those cases coming to autopsy, the meninges are found to be congested. But recovery frequently follows under the influence of gastrointestinal hygienic measures, so that it is easy to understand how these cases have been erroneously classified under the heading of meningitis of gastrointestinal origin.

Sometimes the meningial lesions are more pronounced and the phenomena more serious in character. All these conditions may be due to the invasion of the meninges by germs from the intestines, but the cerebrospinal fluid is often found sterile, as in my case, and under these conditions the toxins are responsible. Again, however, in a number of cases, the assumption of reflex phenomena is favored by the sudden disappearane of the meningial symptoms simultaneously with the removal of the gastrointestinal disturbance. This group of meningitis cases without lesions, will probably become more and more restricted as the pathological processes which give rise to the meningial symptoms become better understood. To illustrate further this type of meningial irritation, Carrière, in Nord médical, reports a case which, in many ways, was similar to the one I have just reported. Carrière observed a case of meningismus in a boy five and a half years of age, who presented a symptom complex extremely suggestive of tuberculous meningitis. The puncture fluid, however, contained neither cellular elements nor microbes. Cultures and animal inoculation remained negative; examination of the blood showed neither leukocytosis nor lymphocytosis, so commonly present in tuberculous meningitis. The child had no symptoms of infectious disease. There was no history of traumatism. In order to eliminate hemihstitialis as a possible cause of meningismus, a prescription of calomel and antimonium was given, but the copious stools which followed contained neither parasites nor ova. Meningismus through autoxenemia of intestinal origin, appeared probable, on account of the patient's tendency to constipation, mucous membranous colitis. The clinical existence of this intestinal autoxenemia was demonstrated by the hypertonic character of the stools, a watery extract of which proved fatal to rabbits. The urine was like-
wise hypertoxic, with increased content of ammonia, indican, and acetone. The influence of this auto- toxication on the cerebrospinal fluid was shown by the fact that a guineaig was killed by one c.c. of the patient's puncture fluid. It has been shown that cerebrospinal fluid from healthy individuals or from patients having bacillary meningitis, has no toxic action on intracranial inoculation into guinea-pigs. The accuracy of the diagnosis was confirmed by the course of the disease. As soon as the internal intoxication had been controlled by suitable measures, the meningismus likewise subsided, together with the signs of this intestinal intoxication. Spinal fluid withdrawn at a subsequent puncture proved to have no toxic effect upon a guineaig. The child was well four days after the institution of the treatment, except for the persisting attack of mucomembranous enterocolitis, which required dieting and other measures.

Bouquet points out that this observation permits the following conclusions to be drawn:

1. Meningal symptoms accurately simulating tuberculous meningitis, and which may be designated as "meningitis," are sometimes observed in children with a neuro-pathic heredity, and in certain cases of gastrointestinal auto-toxication due to colitis or other digestive disturbances.

2. The diagnosis of meningismus may be extremely difficult and require the closest investigation; the clinical picture exactly resembles that of meningitis. The absence of bacillary findings in cases of meningismus is not always an absolute sign. The diagnosis of meningitis cannot always be based on the abruptness of the onset. Photophobia and miosis are observed in meningismus. Irregularity and inequality of the pulse have also been noted. Irregular respiration and dissociation of the thoracic and diaphragmatic movements, often regarded as typical of meningitis, have also been observed in meningismus. An exact diagnosis must be based on the examination of the blood and of the cerebrospinal fluid, with the study of their tension, cellular formula, toxicity, etc., the search for microbes, and animal inoculations.

3. In order to attribute the meningismus to the intestinal auto-toxication, the latter must be established, and this can be done through the investigation of the toxicity of the fecal matter, the toxicity of the urine, the demonstration of amonia, phlegmorrhages, urinorrhages, and acetonuria. The diagnosis is confirmed by the disappearance of the meningismus after the subsidence of these symptoms.

4. The pathogenesis of these meningial complications is explained by demonstration of the toxicity of the cerebrospinal fluid. The fecal impaction and the absorption of the intestinal poisons undoubtedly terminate in hypertoxicity of the serum and of the cerebrospinal fluid. This hypertoxic fluid acts upon the ephalomedullary centres and produces the meningismus. When the intestinal stagnation is relieved, the auto-toxication disappears, and the cerebrospinal fluid loses its toxicity, and the meningismus disappears.

5. The prognosis of this condition is favorable. Recovery must be the rule after the removal of the cause.

6. The treatment is self evident, and includes two indications: 1. Removal of the intestinal auto-toxication by purgatives and enterocolysis, a suitable diet, reducing intestinal fermentation to the minimum. 2. Removal of the toxic action of the blood serum, and especially of the cerebrospinal fluid on the nerve centres, by means of lumbar puncture, repeated if necessary, injections of physiological salt solution, and diuresis.

Appreciation of meningal excitations and of grave nervous disorders, and their etiological bearing upon abnormal decomposition processes in the intestine, is only recently receiving proper attention. The relation of these grave symptoms to decomposition products in the intestinal tract has been proved by clinical observation. As yet, all attempts at isolation of the injurious toxins have been unsuccessful.

SERODIAGNOSIS (ABDERHALDEN) OF CANCER AND PREGNANCY.*

Action of the Protective Ferments in Cancer and Pregnancy.

By C. F. Ball, M.D., Rutland, Vermont.

The fact that a protective ferment is produced for every blood foreign substance opens a field in seropathology that promises to be as important as tissue pathology.

Experimental work with the protective ferments of Abderhalden indicates that this test may be used, not only for the diagnosis of pregnancy, as originally proposed, but for the diagnosis of various diseased conditions. Any physiological condition or disease that causes the blood stream to be invaded by a blood foreign substance, whether physiologically this substance is chorionic villi, or pathologically malignant tumor cells, broken down gland tissue, etc., matters not. The mere presence in the blood stream of these unreduced materials calls for the production of a ferment that will digest them. They are blood foreign so long as they maintain their anatomical structure. The action of the ferments is to digest them, or in other words, to split them into the molecules originally entering into their formation. The molecules in the cell's formation were received from the blood stream as the blood's own substances, and must therefore be returned to their original state. Proteids circulate in the blood only as aminoacids.

In order more fully to understand the action of the protective ferments it will be necessary to review some of the finer processes of proteid digestion. It is the digesting and rebuilding of the proteid elements that interest us most. The peptic of the gastric juice acting in the presence of hydrochloric acid gradually blasts apart the albumin molecule into its coarser constituents, the peptones and proteoses. These latter are still further broken up into peptids and aminoacids by the trypsin of the pancreas and the crepsin of the intestinal mucosa. These are the "building stones" of Abder-
BALL: SERODIAGNOSIS OF CANCER AND PREGNANCY.

The liver stands guard, acting upon any unreduced protein, that no blood foreign elements pass into the circulation. The liver also controls the quantity entering the blood stream and stores that not used.

Every cell, of whatever type, appropriates from the blood stream its proteid requirements of amino-acids in such proportion as that cell finds necessary for its individual economy. Differences in functions necessarily imply variations, chemically and physically, in the structure of the cell’s protoplasm. Although every cell with its neighbor goes to make up the body as a whole, it has, however, an individual life history of its own to maintain.

The lymphatic system guards against the entrance of body cells, as such, either holding them back or reducing their protoplasm to aminoacids or the blood’s own substances.

With these guards always on the alert to protect the blood from invasion, it is possible for its composition to remain fairly constant. There are, however, conditions that upset this equilibrium, and to provide for such an accident the protective ferments are mobilized to make such a readjustment as the condition demands. Any cell accidentally entering the blood stream is blood foreign until separated into the molecules composing it. Even leucocytes and erythrocytes are blood foreign when seriously injured, and are accordingly digested. The combined cell economy produces this special ferment immediately upon the appearance of any blood foreign substance entering the blood stream from whatever cause. When this ferment has been produced, blood from the individual possessing it will digest a similar proteid in a dialyzing thimble kept at body temperature.

The serum of a pregnant woman will digest placental tissue in the dialyzing thimble, because the presence of chorionic villi circulating in her blood, as a blood foreign substance, calls for the production of a ferment to reduce the chorionic cells to their original elements, or aminoacids. Digestion taking place in this thimble is readily detected by heating the dialyze with ninhydrin, which turns the solution a distinct blue violet color upon cooling for thirty minutes.

Investigators are clearly and sufficiently proving the value and reliability of this test in pregnant states. Research to demonstrate that cancer calls for a protective ferment, the same as for pregnancy, and that it can be demonstrated by the same technic, is all important. Sufficient work has not yet been done to warrant the statement that cancerous conditions can be positively diagnosed. That this test appears to be useful in such cases is confirmed by continued experiment with the Aberhalden technic in known malignancies. It is at least safe to say that there has been no test previously devised that runs so positive to a known condition of malignancy, with so high a percentage of positive results. Further, there is no test that runs so uniformly negative to all other conditions. The gravity of the cancer problem demands the association of this test with the experimental production of tumors in animals, by experts possessing suitable facilities, as affording a means of determining the actual value of this test in malignant conditions; the time of appearance and the durability of the protective ferment mobilized by such inoculations would be intensely valuable, as would be the determination of the length of time the special ferment might persist after the radical removal of the tumor. I firmly believe that this work will soon be done and that the results will be very gratifying and the information obtained will go a long way toward solving the cancer problem.

An attempt has been made in bringing together the following abstracts to show, first, the probable merits of the Aberhalden technic in cancer diagnosis as compared with other serum tests now in limited use, and secondly, to suggest the inference from work already done that the test may be as definite in malignant conditions as is the test in pregnancy.

The mostagamin reaction of Ascoli, while giving good results in his hands and the hands of his associates, fails to be satisfactory in the hands of equally careful men.

Bruggemann (1) reports the Ascoli test positive in twenty-one out of forty cancer cases. He also used the Kelling hemolysit test, which gave positive results in twenty cases out of forty. In only twelve of the cases were the two positive together.

Halpern (2), using von Dungern’s complement deviation test, reports 89.8 per cent, positive reactions in seventy-nine carcinomata patients, and 92.8 per cent, negative in fifty-six patients free from tumors.

Arzt and Kerl’s (3) tabulation of various serodiagnostic tests (other than that of Aberhalden) gives the following figures and average of eleven different workers; with the mostagamin reaction, 82.8 per cent, of positive reactions in three hundred and ninety-nine cases of cancer, and 9.5 per cent, positive findings in five hundred and forty-eight healthy persons: working with the Freund-Kaminar reaction obtained positive findings in eighty-three per cent, of fifty-three cases of cancer, and 13.5 per cent, positive in sixteen cases with other affections. Ascoli, personally, obtained ninety-three per cent, of positive findings with his mostagamin test in his series of one hundred cases.

Epstein (4) (working with the Aberhalden technic), using carefully prepared carcinomata tissue, with a control test of placental tissue, found that in thirty-seven cases of cancer the serum of all but one reacted positively with cancer tissue, negatively with placental tissue. In seventeen out of eighteen cases, serum of pregnant women reacted positively with placental tissue. Of forty-seven other cases, free from cancer, but with some other severe disease, forty-six reacted negatively with cancer tissue. Epstein consider the test of great importance.

Frank and Heimann (5) obtained a positive reaction in fifty-three out of fifty-four cancer cases, or 98.2 per cent., while the reaction was negative in five per cent. of twenty normal persons. The tissue of cancer of the uterus was used in these tests.

Markus (6) reports eleven cases of carcinomata tested by Aberhalden’s method—the results all corroborative.
From the fact that the Abderhalden technic had been in use for only a few months compared with the tests above mentioned, it is not safe to arrive at the conclusion that because a few workers get favorable percentages with this method, the test is inevitably that much better. As a possible index as to the value of the test in future cancer work and as showing the value in pregnant conditions, the following abstracts of over two thousand cases are significant.

Abderhalden (7) reports three hundred cases of pregnancy with exact technic in which there was not a single negative reaction.

Lindig (8) had confirmed Abderhalden's results in his tests. He regards it as having "established beyond question now that a proteolytic ferment is present in the blood serum of pregnant women, and in women with tumors in the genital tract, and possibly also with inflammatory processes. This ferment is able to digest the albumin in placenta, uterus, and ovarian tissue, in tissue from tumors of the genital organs, and to a less degree, muscle albumin."

Parsamow (9) made one hundred tests with Abderhalden's earlier technic and sixteen with his later technic. He found the reaction positive in all cases of pregnancy, but also in some other cases, especially those with cyst, myoma, and some cases of cancer. He believes, therefore, that the test is not absolutely specific, but may be useful in differential diagnosis in some cases—a negative reaction shows that there is no pregnancy, but a positive reaction is not absolutely a proof of pregnancy. He thinks that further perfection in the technic may make the test more reliable.

Schlimpert and Hendry (10) used Abderhalden's biological test for pregnancy soon after the publication of the method, and report the results in three hundred and sixteen cases. At first their findings were contradictory, but they found the hydrant water (Freiburg) used, to be the source of error, and since this was eliminated their results confirmed Abderhalden's statements. They based their conclusions on the last series of seventy-nine patients, forty pregnant and thirty-nine nonpregnant. In these they found the reaction strictly specific, and they believe it to be the "greatest progress yet made in the investigation of the metabolic processes which accompany pregnancy." They obtained the sera in all cases while the patients were fasting, and included patients with various diseases in their nonpregnant cases.

Jellinghaus and Losee regard the accuracy of the method and the results in these seventy-nine cases as "unimpeachable."

Stange (11) reports positive findings in all of seventy-three of his cases of pregnancy.

Heinmann's (12) experience with one hundred cases confirms in every respect Abderhalden's statements in regard to the serodiagnosis of pregnancy.

Behne (13) did not find the dialysis test absolutely specific for pregnancy. He tested one hundred cases, but leaves out of consideration the first forty in which the technic may have been defective. He found the reaction almost constantly positive in normal pregnant women, but in a few instances it was negative where pregnancy was certain. He also found it positive with a number of nonpregnant women with an inflammatory process in the genital organs or elsewhere: and also positive in several males but only in cases with pulmonary tuberculosis or liver disease.

Elker (14) finds Abderhalden's test very reliable, and considers it of especial importance in the diagnosis of early pregnancy, extraterine gestation, and amenorrhea at the time of the climacteric.

Engelhorn (15), who followed Abderhalden's technic carefully (?) in regard to the preparation of placenta and the blood serum, obtained unsatisfactory results. In sixty pregnant women, he obtained a positive reaction in forty-nine, negative in eleven; in forty-eight nonpregnant cases, positive in thirty-one, negative in seventeen. He also tested the serum of pregnant women twelve times with cancer tissue, obtaining a positive reaction ten times, a negative reaction two times; sera of nonpregnant women were positive three times, negative three times. He concludes that the test is not specific. Engelhorn is the chief opponent of Abderhalden's test.

Freund and Brahm (16) used both the dialysis and the optic method in their test. "The findings were sustained by the clinical aspect of the case in 72.4 per cent. of the one hundred and thirty-four cases in which the optical method was applied and 66.7 per cent. of the ninety-nine cases with the dialysis method. The fresher the serum, the better the chances for accuracy in the test. In the ninety-two cases in which both methods were applied, the findings harmonized in sixty-one instances, including forty-three positive and eighteen negative cases. In thirty-one cases the findings were contradictory. These authors believe that by neither method is one able to determine beyond a doubt the existence of pregnancy, yet the scientific importance of the reaction involved is still very great."

Heiiner and Petri (17) come to the conclusion that the serum of pregnant women will give a positive reaction, but that other sera will also give a positive reaction, with placental as well as with other tissue; also that the serum of pregnancy will give a positive reaction with tissue other than placental. Hence the reaction is not specific.

Maccabruni (18) had tested over one hundred cases with both the dialysis and the optical method, following Abderhalden's technic carefully. Out of eighty-four pregnant cases, he obtained only one negative and three doubtful or weakly positive reactions; in one nonpregnant case with cystic ovary, the reaction was positive. The author does not consider that these results affect the practical value of the test. He also used the dialysis test with fetal serum, with a positive reaction in some cases. He suggests that the fetus may have some part in the formation of the protective enzymes, but does not consider that sufficient experiments have been made to prove or disprove this point.

Murray (19) gives a brief notice of Abderhalden's method but adds nothing of importance.

Petri (20) has found Abderhalden's method very reliable in determining the existence of pregnancy. It gives information before any other method per-
mits "even a presumptive diagnosis." Even a few days after the imbedding of the ovum it may be possible to determine the specific ferment and thus establish the presence of gestation. "In experimental tests with placental tissue, he found a positive reaction seven or eight hours after subcutaneous injection, and fifteen minutes after intravenous injection."

Rubsamen (21) used the Abderhalden test one hundred times. In ninety-four cases, thirty-eight tests were made by the dialysis method alone, six by the optical method alone, and fifty-six by both methods. Of these, forty-seven cases were normal pregnant women; the reaction was positive in all; most markedly so in the first half of the pregnancy. The author comes to the conclusion that the Abderhalden reaction is entirely reliable as a method of diagnosing pregnancy.

Schiff (22) emphasizes the importance of thoroughly understanding Abderhalden's technic and of following it carefully. He tested forty-nine cases by the dialysis method (ninhydrin reaction) and obtained a positive reaction in all cases of pregnancy, and a negative reaction where there was no pregnancy. In addition he obtained a negative reaction where there was no pregnancy. In addition he obtained a negative reaction where he used carcinoma tissue with a pregnancy serum. He believes the method to be of the greatest value.

Veit (23) in a recent article stated that he considers Abderhalden's method important from a clinical standpoint for the early diagnosis of pregnancy, and from a theoretical standpoint for the further study of the normal and pathological physiology of pregnancy.

Aschner gives the following statements from Veit's clinic: Forty-five cases from the second half of pregnancy gave positive reaction. Of sixteen cases from the first half of pregnancy, including abortions, fourteen cases gave a positive, two a negative result. A control test by Abderhalden himself for one of these two gave a positive result; no control test in the other case. Twelve normal nonpregnant cases gave negative reactions. Of fourteen tests of cancer of the uterus, eight were negative, three were positive with the dialysis test, negative with the optical test; three were slightly positive with the dialysis test (no optical test). Four cases of myoma were negative. Of four cases of hemorrhage in the climacteric due to metritis, two gave a positive reaction, one a weakly positive reaction, and one a negative reaction. Of five cases of amenorrhea in the climacteric, four gave a negative reaction, two a positive reaction with the dialysis method, one of the latter being negative with the optical test. Six cases of chlorosis gave a negative reaction. Of twenty-three cases of anamnestic disease, seventeen were negative, two positive and the rest weakly positive. Aschner stated that his statistics show five per cent. of failure to obtain the correct diagnosis from the test, which may in some cases be due to some slight fault in the technic. He believes Abderhalden's method to be useful, but is not prepared to say that it is absolutely specific.

Schwarz (24-25) says: "While using the biuret reaction exclusively, I had some negative results in cases of advanced pregnancy, because digestion was carried too far; since using the ninhydrin reaction I have obtained positive results in some non-pregnant cases, because I worked with too large quantities of serum; at all times I have had conflicting results due to various sources of error such as bacterial growth, unclean glassware, leaky dialyzers, and improperly prepared albumin."

"On the other hand, I have the records of twenty-one pregnant and four puerperal cases, in which the test invariably has given the violet blue ninhydrin reaction, while the control remained colorless. . . . I also have the records of eighteen nonpregnant cases, including several tubal enlargements, four uterine fibroids, and two males, in which the dialyzates of both test and control remained colorless. . . . In eight instances the serodiagnosis has been employed as the only means of differential diagnosis and in every one of these eight cases, its answers have been true."

Williams and Pearce (26) found that the dialysis test or ninhydrin reaction positive in twenty-eight pregnant women, and three women in the post partum period, including one abortion. "The test has never been negative in any known pregnancy. On the other hand, the serum of pregnancy reacts with tissues (kidney, heart, uterus) other than placenta; also sera of two cases of nephritis, one of tubas and one of infection (carbuncle), and occasionally of individuals apparently in perfect health have given the reaction with placenta and other tissues. Inactivation of the serum causes a great diminution in the degree of the reaction, but does not cause it to disappear entirely." These authors conclude that "this test cannot be accepted as an accurate clinical method until it has been thoroughly investigated and the possible sources of error corrected." This conclusion applies only to the dialis- is method, not to the optical method, which they have not tried.

Schwarz says that the investigations of Williams and Pearce are "absolutely worthless and must be entirely discarded on account of faulty technic."

Jellinghaus and Losee (27) used the dialysis test for five hundred and sixty-three sera; they did not have results that proved the dialysis test to be absolutely specific for pregnancy, but as they progressively improved their technic, the results became more and more accurate, showing that much depends upon the absolute accuracy of the technic, and many failures to obtain correct results are to be attributed to lack of attention to the details of the method. Hence these authors "favor the opinion that it is possible by the dialysis method to distinguish between the healthy pregnant and the healthy nonpregnant woman."

Judd (28) reviews the technic, but reports no cases. In a second article (29) dealing largely with its pitfalls, he finds the test with his improved technic in a variety of different cases confirmatory of Abderhalden's assertions. He finds the test the same in pregnant colored women as it is in white women. He finds many diseased conditions negative to placental tissue, including one case of cancer of the cervix, several infectious diseases, typhoid, septicemia, pericarditis, endocarditis, and gonor-
rheal arthritis, all negative to placental tissues.

Gutman and Druskirn (30) performed three hundred and fifty-seven tests with the dialysis method on two hundred and two cases. In their earlier series of cases, they had some difficulty with the details of the technic, but after carefully reviewing and correcting their methods of procedure, they obtained results that showed the test to be very reliable. The last group, in which the technic was perfected, comprised one hundred and fifty-nine tests in one hundred and six cases, with ninety-eight per cent of correct findings. The two cases in which the findings were incorrect were a male syphilitic, with positive Wassermann, which gave an indistinct biuret and a doubtful ninhydrin reaction; and a case of ectopic gestation which gave a negative reaction. Of the one hundred and six cases, seventy-nine were pregnant and twenty-seven were nonpregnant (including eleven males).

McCord (31) used the Abderhalden test in two hundred and forty cases with practically no failure. He believes that "the serodiagnosis of pregnancy is both reliable and practical."

Jamison and Cole (32) tabulate fifty cases of all kinds as follows: Three cases, seven to nine months pregnant reacted positively to placental tissues. Three normal gave a positive reaction. Two ectopic gave a positive reaction. Two abortion cases, one about six months, the other two months, gave each a positive reaction. One stillbirth gave a negative reaction. A case of pernicious vomiting gave a positive reaction. One case, nonpregnant, in the menopause gave a negative reaction. Ten females and thirteen males with various diseases all reacted negatively. One case of acute nephritis in a woman reacted positively. One case reacted positively after eating.

Heaney and Davis (33) with corrected technic report one positive case of five nonpregnant and four cases with a negative reaction. Of seven pregnant women two negative reactions, six and fourteen weeks respectively; three positive reactions in early puerperium with two negative in later puerperium, thirteen to twenty days respectively.

Steising (34) has announced that he has succeeded in separating the active ferment into an amboceptor and a complement test, which renders the technic much more generally applicable. He inactivates the serum by heating to 50° C. for an hour and then reactivates it as desired by the addition of fresh male serum.

Mayer (35) declares that the contradictory findings reported by some experimenters with Abderhalden's technic are due to the fact that practitioners as a rule are not used to painstaking exactness or chemically pure methods, consequently conflicting results are obtained merely because some imperfection has crept into the technic. With increased care and practice, the conflicting findings grow less and less frequent. The clinical importance of this serodiagnosis of pregnancy is obvious, not only at its earliest inception, but also after all other signs of it have subsided, as after abortion. In a case described, the suspicion of a recent abortion apparently was not confirmed by the scrapings of the uterus, but the serodiagnosis was positive. Renewed examination of the scrapings finally revealed decidual tissue. The reaction is positive with an extraterine as with a normal gestation, but it becomes negative in both after the tissues, especially connected with the pregnancy have lost their vitality from the death of the fetus. Mayer reports further research with the test applied to eclampsia and various complications of pregnancy. The response shows that the protective ferment involved keep constant, as in the behavior of the blood. The response to the test also throws light on the functioning of glands with an internal secretion, also on metabolic disturbances and on cancer, as he illustrates with cases from his own experience. He suggests further that it may prove interesting to study racial differences in the reaction to the biological tests.

The results (36) in my first series of cases, using a cancer proteid prepared from a lymphosarcoma involving the retroperitoneal glands will be quoted as follows: "The serum from each patient was run both with placental and tumor tissue. Three cases of a known malignancy reacted positively to a sarcoma proteid: one, a carcinoma of the uterus, inoperable; one, a carcinoma of the sigmoid, confirmed by the x ray; one, a postoperative carcinoma of the cervix (four months after operation). Two cases were examined for a doubtful malignancy, one of the stomach, and the other of the liver. In each case the test was clearly negative.

One of two cases consulting me more than a year ago for cancer of the breast, gave a positive reaction, the other was negative. In both cases the "questionable bunches" were not considered malignant at the time. In the case giving a positive malignant test, the blood serum also reacted to a placental tissue as the woman had just given birth to a child. Consequently there appears in this instance two ferments, one reacting to tumor tissue and the other to placental tissue, or one ferment digesting two different kinds of proteids. In this series I have a second parturient giving a double ferment, and one male. I know nothing of the second woman's history, as I attended her for one of my associates when he was on his vacation. Questions on my part brought out nothing so far as any possible history of malignancy was concerned. The man with the double ferment referred to, had been treated for some time for a papilloma of the bladder. He gave a history of a rapid loss of weight and strength during the few months previous to the test.

"One has to ask the question: Will tumors of the genital tract cause the production of a ferment that will digest placental tissue as readily as cancer proteids? Lindig found a ferment in women, with tumors of the genital tract, that digested placental, uterine, and ovarian tissues. In this male there is evidently a similar ferment to that found by Lindig in women."

"In these malignancy tests there was not the suggestion of any reaction to placental tissue except in the two parturients referred to and this male."

"Of seven known pregnancies all have reacted positively. Of four tests made to determine a possi-
ble pregnancy, three showed an illogical condition. The fourth case presented gave acute abdominal symptoms, with an apparently enlarged uterus. The test failed to show positively to placental tissue. Operation revealed a pronounced tuberculous peritonitis, with a nongravid uterus. In all the cases where the test was made primarily with placental tissue the control was always negative to carcinoma tissue, except as already mentioned.

"The results were further controlled by using separate thimbles of blood serum, alone; tumor tissue with distilled water; and formaldehyde or heat to inactivate the serum. These controls were always negative or the test was discarded. In one test all the thimbles went bad on account of using old distilled water. In this test the formaldehyde thimble was not used. The test was repeated with fresh distilled water, and gave a satisfactory reaction. As a result of this failure, I have set up a still to furnish perfectly safe water as required.

"Another fault experienced in one of my early cases was my failure to rebol the tissue and have it test negatively to ninhydrin, before use. As a result of this carelessness I obtained a positive reaction in a male. Correcting the error, I received satisfactory and correct results. A second male with a history of gonorrhea reacted negatively to all tissues used."

My further work with the different kinds of tumor tissues appears to make the diagnosis of cancer rather more complicated than suspected, but more interesting, inasmuch as there appears a possibility of being able to designate the kind of tissues involved. I have been led to think of such a possibility when comparing the clear cut differences of reaction in my first series of cases, using the sarcoma proteid, compared with subsequent tests made with the proteid prepared from an epithelium of the cervix. When using this kind of material I was not able to get satisfactory results. Pregnant conditions would, apparently, give the malignancy reaction in cases known not to be malignant, probably because of the ability of the pregnant ferment to digest uterine tissue as well as placental tissue. I believe this is also an explanation for some of the adverse findings by others giving their reports, but not specifying the kinds of tissues used. The same result was obtained when using albumin prepared from an epithelium of the skin of the hand. I used this tissue only a very few times, fearing to continue on account of the possibility of the sweat glands complicating the test. I am convinced that some of the conflicting reports relative to the value of the test are due to the use of different and poorly prepared materials. It is interesting to note that Engelhorn obtained ten positive reactions out of twelve pregnant cases using cancer tissue (probably a uterine malignancy of some kind according to results obtained by others with pregnant sera). It is not impossible from his results with nonpregnant sera, eight positive with only three negative, that his trouble was due to poorly prepared placental albumin. Personally I believe the latter to be the cause of his unusual findings, which opinion is supported by his poor record with the pregnancy test compared with so many others getting satisfactory results.

Schiff failed to get any reaction with cancer tissues in pregnant conditions. He does not state the number thus examined, or the kind of cancer tissue used. Markus states that he gets positive findings in all of eleven cases of cancer. He does not state that his pregnant cases were negative to the tissue used for his cancer work.

Veit reports in his series of pregnant cases fourteen cases of cancer of the uterus, of which eight were negative to placental tissues, three positive by dialysis method, negative by optical method, with three others slightly positive by either test.

It remains for Epstein, Frank and Heimann to supply us with satisfactory and correct results. Epstein worked with the two tissues at the same time, obtaining very satisfactory results. Frank and Heimann worked with the cancer tissue alone, getting 98 per cent. positive reactions in known cancer cases and ninety-five per cent. negative findings in twenty normal individuals.

In conclusion, I desire to emphasize: 1. The desirability of always working with at least two kinds of tissues, one of these necessarily to be carefully prepared placenta; 2. the necessity of designating the kind of material used in all experimental work when other than placental tissue is used; 3. the advisability of associating this test with experimental tumor transplantations in animals; and, 4. further experimental work directed toward determining, if possible, all sources of error in the present technic, or the substitution of a trustworthy modification.

BIBLIOGRAPHY:

chronic suppuration of the middle ear. A consideration from the standpoint of the general practitioner. By J. Auerbach, M. D. New York.

Paradoxical as it may seem, specialization has increased rather than diminished some of the responsibilities of the general practitioner. To-day his scope is broader than ever, an extensive acquaintance with the resources and limitations of the special departments of medicine is absolutely essential to him as well as the relation which each of them bears to his own work. The specialist, however, his mind focused on his own special subject no longer looks out upon the broader horizon of general medicine.

Fortunately the influence of the general practitioner has in wiselesssenened, notwithstanding the fact that much surgical and medical treatment is carried out by the various specialists. Patients still continue to consult the family physician and to act upon his advice in reference to surgical procedures or special treatment. It therefore devolves upon the general practitioner to recognize the early symptoms of disease and to place them in their proper category. We may conclude that it is just as important for the general practitioner to detect these early signs as it is for the specialist or surgeon to apply the means of cure.

There are few diseases of the ear which the general practitioner is so frequently called upon to observe as the chronic discharging ear, or as it is commonly called, the O. M. P. C. In fact, it is he, who, in the majority of instances, will be called upon for a diagnosis and for treatment long before the patient thinks of consulting the otologist. Often, too, he will be consulted for symptoms which the patient does not attribute to his ear condition, but which symptoms have a direct bearing on the suppurative process.

Suppurations of the middle ear may be acute, subacute or chronic; I shall not dwell upon the acute or subacute variety of middle ear discharge, but will consider the chronic type from the clinical and diagnostic standpoint. For a thorough appreciation of the pathology of chronic middle suppuration, one must take into consideration the causes which lead to chronicity; among these causes may be mentioned the general systemic diseases, as tuberculosis, syphilis, the severe anemias and malnutrition in general, and local causes, such as chronic affections of the nose and throat. Certain anatomical conditions are also influential factors in predisposing to chronicity, such as perforations in Schrapnell’s membrane and affections of the attic, a region which is clothed with numerous mucous membrane folds and ligaments, and where stagnation may easily take place. Certain forms of acute otitis have from their virulence a tendency to become chronic from the very beginning of the infection; I have reference especially to the severe otitis media accompanying the acute infectious diseases, as measles and scarlet fever. Chronic inflammatory processes in the external auditory canal, as chronic eczema, may, by extension into the tympanic cavity or by narrowing the lumen of the canal, prolong the middle ear discharge.

Pathologically and clinically speaking, chronic middle ear suppuration may be divided into two chief classes: First, the benign uncomplicated or when there is involvement only of the mucous membrane of the tympanic cavity; second, the complicated or malignant cases where, in addition to involvement of the mucous membrane, there is also involvement of the bony structures of the ear organ and of those bony structures which separate the ear organ from the middle and posterior fossa of the skull. To this class of cases also belongs that form of middle ear suppuration accompanied with cholesterol.

A chronic suppurring ear is at best a menace to the patient, but fortunately there are many cases which are amenable to conservative treatment, and these are the uncomplicated or benign cases; here, as I have said before, there is involvement of the lining membrane only; function of the sound conducting apparatus alone is interfered with, and the dangers of intracranial complications, which may arise, are at a minimum.

In the complicated middle ear suppurations the pathological changes are such as not only to threaten the organ of hearing, but to produce complications which endanger the life of the individual. It becomes of primary importance, therefore, to recognize those signs or symptoms which are evidence of approaching danger, and which will indicate the proper method of procedure. The structural change underlying the chronic complicated suppurations are varied; there is primarily, in addition to the inflammatory process involving the mucous membrane of the tympanic cavity, an accompanying structural change in the bony skeleton of the ear and of the ossicles, the latter often becoming necrotic, the antrum and mastoid cells become involved, and from here the inflammatory process may extend into the compact mass forming the facial canal. In the tympanum proper we have, forming the inner wall, the promontory representing the basal turn of the cochlea; the oval window receiving the foot plate of the stapes and leading directly into the vestibule of the labyrinth; above it, the horizontal portion of the facial nerve: below, in the posterior inferior quadrant,
the secondary drum membrane or round window, leading directly into the membranous cochlea.

In the epitympanum or attic, there are housed the malleus and incus and its thin roof separating the tympanum from the middle fossa of the skull; furthermore the horizontal or external semicircular canal, lying partly in the antrum, is unduly exposed to any necrotic process in the immediate vicinity. I mention these anatomical facts in illustration of the vast number of important structures that may become involved in the course of a middle ear suppuration, and a detailed knowledge of which becomes absolutely essential, not only in the surgical treatment of these complications, but for the proper interpretation of the clinical symptoms which we shall soon analyze.

Simple noncomplicated suppurations of the middle ear are characterized by the mildness of their course, the chief symptoms being otorrhea of long standing, sensations of fullness in the ear or in the head, and subjective noises; otoscopic examination, after cleansing the external auditory canal, discloses a perforation in the drum, generally of large size, either central or marginal, through which may be seen the velvety shiny membrane of the tympanic cavity; the secretion in neglected cases is fetid, while those receiving proper, systematic treatment are on the other hand never so. The bony external auditory meatus is intact; the ossicular chain and mastoid are unaltered and the pus drains freely, or there may be slight retention. Especially is this apt to occur in the presence of granulations or polypoid masses, when these excrescences of mucous membrane prostride through the perforation in the drum and act as a barrier to the free exit of the pus. The functional tests show all the signs of interference with the sound conducting apparatus, with more or less diminution in the hearing.

In the course of a chronic middle ear suppuration when the diseased process has extended to the surrounding and underlying structures by means of the various paths outlined above, it becomes imperative to recognize as early as possible the invasion of the purulent process into the danger zone. To emphasize some of the signs of impending danger that the process may be nipped in the bud, so to speak, shall be the aim of the writer, and if he can make these points clear, he will offer no words of apology for the presentation of a subject which has trodden the beaten path.

A form of chronic otitis media that should put one on guard and be shown the respect which it deserves is that type of suppuration in which there is a tiny perforation in Schiapnell's membrane; perforations in this portion of the membrana tympani are of necessity small, because Schiapnell's membrane in its entirety is small compared to the membrana flaccida. The location of the perforation is a strong index to the seat of the suppuration, and in every case where Schiapnell's membrane is found perforated, it is safe to assume that the attic is involved; drainage through a small perforation in the upper part of the drum cannot be complete, with the result that retention and stagnation occur; the ossicular chain and the numerous folds and ligaments are bathed in the pus, and the field is now a favorable one for necrosis; this often does take place, resulting in great diminution in the function of hearing, fetid odor and headache. A continuation of the process may result in exfoliation of the ossicles, and the pus traveling in the direction of least resistance, may invade this plate of bone separating the attic from the middle fossa of the skull; sometimes this plate is cellular, sometimes, especially in young children, dehiscences may exist, this hastening the spread of the infection to the meninges.

Among the conditions complicating chronic middle ear suppurations may be mentioned cholesteatoma, chronic periostitis, latent mastoiditis, facial paralysis, labyrinthine and sinus affections, and involvement of the structures in the middle and posterior fossa.

Cases associated with cholesteatomas are especially worthy of consideration, because of the tendency of the cholesteatomatous masses to invade the deeper structures. Their presence should sound a note of warning, and be looked upon as an important danger signal. The subject of cholesteatoma is a large and interesting one, but it is not within the scope of this paper to consider it in detail; I will say in passing, however, that every chronic discharging ear should be examined for their presence, and particularly those cases showing marginal perforations of the drum, because it is here that the proliferation of the epithelial masses from the external auditory canal can gain easy access to the tympanic cavity.

I have mentioned headaches in speaking of attic suppuration; I cannot lay too much stress upon this symptom of complicated middle ear suppuration, and where this is constant and localized over the parietal occipital region, in spite of free drainage, it is probable that the process has extended to the dura of the middle or posterior fossa.

In recent years much effort has been expended in the study of the labyrinth and the various modes of attacking it when it is the seat of a suppurrative inflammation; its close anatomical association with the meninges and the brain proper is sufficient to give prominence to this organ, if only from the standpoint of preventing the spread of infection from the labyrinthine spaces to the coverings of the brain. It is not my purpose to go into the various forms of labyrinthitis, but as this organ is never the seat of a primary inflammation, which is almost always secondary to an otitis media, it may not be amiss to point out the cardinal symptoms of labyrinthine irritation as they may occur in the course of a chronic middle ear suppuration. These symptoms are: First, vertigo; second, nystagmus; third, nausea and vomiting; fourth, disturbance of equilibrium; and fifth, disturbance of the function of hearing.

Vertigo associated with chronic middle ear suppuration should at once direct the attention of the examiner to the state of the labyrinthine function. Labyrinthine vertigo is differentiated from other forms of vertigo in that it is always associated with subjective sensations of turning, is influenced by movements of the head, never accompanied with loss of consciousness, and is not influenced by closure of the eyes. The nystagmus is made up of two components: one quick, the other slow; the former is cortical in origin, while the latter is of labyrinthine origin. The dizziness in most cases is
in proportion to the degree of nystagmus; the more marked the nystagmus, the more marked the dizziness. Naturally, nystagmus due to other causes must not be lost sight of, such as the nystagmus produced by disorders of the eye and its muscles, by cerebellar diseases, by neurasthenia, etc.

Attacks of nausea and vomiting coming on in the course of a middle ear suppuration may be due to concomitant disease of the stomach; the close observer, however, will remember the reflex irritability of that organ which may be produced by inflammatory processes when they invade the inner ear or meninges; this statement will probably recall to many the attacks of nausea and vomiting which have ushered in infections of the middle ear in children.

Disturbance of equilibrium as a sign of invasion of the labyrinth is produced by the abnormal irritation of the vestibular end plates in the semicircular canals, these being the special end organs of the semicircular canals, as Cortis's organ is the special sense organ of the cochlea. This disturbance of equilibrium has a special character, in that the falling is always opposite to the direction of the nystagmus; in other words, in the direction of the slow component. The falling may be to the diseased side or to the healthy side, depending on the stage of the infection; in general it may be said that in the beginning the falling is away from the diseased side as the nystagmus is then directed to the affected side.

Disturbance in the function of hearing. This is not as important a symptom as those mentioned above, as the hearing is already affected in the middle ear suppuration. I must lay stress upon one point regarding the loss of hearing; that where this is sudden and complete and comes on in the course of a middle ear suppuration, invasion of the cochlear portion of the labyrinth is manifest.

In the light of the present day crusade that is being made against tuberculosis, I cannot refrain before closing my paper from saying a few words about tuberculous otitis media. This is a form of middle ear affection which is pretty generally overlooked; but if it is remembered that supplicative otitis media of tuberculous origin begins without inflammatory phenomena, without the usual manifestations of pain or tenderness, that the first thing the patient is aware of is discharge from the ear, that in addition the drum shows multiple perforations, many discharging ears looked upon as belonging to the ordinary variety will be properly classified.

62 West Ninety-Sixth Street.

THE RESORTS WE VISITED.*

By Howard Paxton Collings, B. S., M. D.,
Hot Springs, Arkansas.

For years many of us who heretofore had not visited any of the famous European spas had a great desire to do so, that we might learn personally of the efficiency of their waters, and view the many attractions and advantages at these places which induce so many Americans to visit them each season. The members of the American Medical Travel Study Tour who visited several of these resorts on their tour this summer were fortunate indeed. They were accorded a most cordial reception at each place by the local medical fraternity and by the officials, and were given by them every opportunity possible to study the mineral waters, the various methods of treatment of disease by the use of these waters, and also to inspect the various beautiful bathing establishments and Kurhäuser. No task was too great nor was time spared by these generous people to further the object of our visit, and it is with the most profound feeling of gratitude that these many courtesies are acknowledged.

The first resort visited was the spa Baden near Vienna which is one of three places that were named Baden by the Romans. One of these is situated in Switzerland, one on the Rhine in the Grand Duchy of Baden, and the third is the one of which we are writing.

Baden is a beautiful little city about forty minutes by train to the south of Vienna, admirably situated on the plain of Wiener-Neustadt and on the slopes of the Wienerwald. Its inhabitants number about 22,000, with an additional annual patronage of over 30,000 who take the "cure"; in addition there are many excursionists each season who stay for a short period to view the many attractions of this noted resort and to delve into its history, which is so replete in its associations with great men and great deeds of the past.

For over two thousand years it is known that these thermal sulphur springs have been used for the cure of disease. The overfed, gouty and rheumatic Romans made this a convenient stopping place in order that they might gain a new lease on life. When they were driven southward other nations took their place so that, on and on down through the centuries to the present, these springs have had their bosts with disease and doubtless more often won than failed.

There are thirteen springs in all, ranging in temperature from 84.3° to 96.8° F., and yielding upward of 6,000,000 litres of water daily. The water itself is decidedly sulphosaline, not unpleasant to taste, however, and it is radioactive. There are also thirteen bathhouses, among the newest being the municipal Hotel Herzogshof, completed in 1909 on the site of a former one of the same name. The Sanatorium Gutenbrunn is a beautiful, thoroughly equipped institution with bath house, where all the modern methods of balneotherapy are used.

At our next stopping place—Marienbad, which is situated in the western part of Bohemia—conditions are somewhat different. The springs are dissimilar to those of Baden and are owned by the abbey of Tepl, which in itself is an innovation, and the use of the waters for curative purposes is comparatively recent. Prior to 1818 they were little known and in fact as late as 1779 the site that Marienbad now occupies was a part of the dense forest possessions of the abbey of Tepl. What a contrast to-day! A beautiful, substantially built city greeted us, remarkably uniform in its architecture, and all looked so symmetrical, modern, and

*I am indebted to Dr. S. P. Collings for valuable assistance in gathering data for this article.
well kept. It is partly surrounded and protected by pine covered hills, over which are beautiful foot paths leading in every direction.

There are ten principal springs in all, with an enormous aggregate flow of mineral water. The Marienquelle, which we visited, was notably large, and it was an interesting sight to see the water babbling up from all over the bottom of a capacious rectangular enclosure. Had the water not been cold, as all these spring waters are, we might have received the impression that Satan was not far away and was just giving a demonstration of how thoroughly well he could make water boil.

The waters from the different springs here vary considerably in their analyses. This gives to the place a great advantage in their therapeutical application. Some contain large proportions of Glauber's salt; others are rich in carbonate of iron, and all are highly charged with carbonic acid. The Ferdinandsbrunn contains the largest amounts of sulphate of soda (47.0 parts per 10,000), chloride of sodium (17.0), bicarbonate of sodium (20.0), bicarbonates of calcium and magnesium (6.0) each; and clear carbonic acid (3.1). From this analysis the sulphate, chloride and bicarbonate of sodium decreases gradually in the other springs to almost nothing but the carbonic acid and bicarbonate of calcium content continue in all nearly the same; two contain a large percentage of bicarbonate of iron. From the waters salts are also extracted, which are shipped to all parts under the name of Tepler salts and some of the natural waters are also shipped extensively for drinking purposes.

Space does not permit of our going into detail concerning the large and beautiful bath houses, the extensive and well appointed kurhaus, and the splendid colonnades. Suffice it to say, however, that there are three very large modern bathing establishments in which every variety of bath may be given. The mud bath facilities are extensive, the mud used being of a ferruginous and sulphurous variety obtained near at hand.

Reluctantly we departed from peaceful and beautiful Marienbad, but as we approached the world renowned Carlsbad, our next stopping place, our interest naturally centred there. It is the one resort of the Continent that is best known to Americans and greater numbers go there for the "cure" each year than to any of the others. Carlsbad is situated in the northwestern part of Bohemia in the valley of the Tepl. The Eger river passes by the town and separates it from Fischern which lies just over the bridge. The Tepl river runs through it, and the city itself seems crowded in the narrow valley, close to the banks of this small stream, which should be arched over. However, there are 3,500 acres of park woodland in the adjoining hills that serve as a strolling place for those who are well enough to undertake the grades. The altitude, 1,227 feet above sealevel, is ideal. It lightens the air sufficiently to encourage the deep breathing in of the pine laden zephyrs, wafted from the forest covered hills.

There are sixteen mineral springs used in the "cures." These range in temperature from 102.2° to 163.4° F.; the hottest as well as the most productive is the Sprudel spring, which has a flow exceeding 2,000 litres a minute. The analyses of the various springs show the solid contents to be very nearly the same, there being a great difference, however, in the carbonic acid content and the temperature, the waters of lower temperature as a rule having larger proportions of carbonic acid and also greater radioactivity. Both the water and the gas issuing therefrom are radioactive. The carbonate and sulphate of sodium and chloride of sodium are the predominating salts contained in the water as well as a considerable portion of hydrocarbonate of lithium.

The springs are owned by the city as are also the five large bath houses. The kurhaus is a very extensive building, erected in 1867, containing 166 rooms, apportioned as follows: Thirty-five for Sprudel water baths, thirty-eight for carbonic acid baths, fifty for mud baths, forty-three for mud packs and the great halls of the kurhaus. The Kaiserbad, erected in 1805, much more modern than the above, contains the most extensive Zander's system department that we saw. The room was very large and indeed stately, containing sixty-five appliances. The Elisabethbad, completed in 1906, is an impressive looking building both inside and out. It has the advantage of an open park in front which, together with its newness, makes it very attractive. We also visited the Sprudel salt works and were shown every detail of their manufacture.

From Carlsbad an autobus line landed us, in the course of an hour's time, at St. Joachimstal, one of the most talked of places in the world by students of radium and radium emanation.

The surrounding country here is mountainous in character and was noted for centuries for its silver mines. The chief product now, however, is uranium pitchblende, from which radium is obtained. These mines are the greatest uranium ore producers in the world and unless recent discoveries in Colorado come up to expectations they will probably continue to be such.

The Austrian government is the owner of these mines and likewise of the springs which exist in various parts of them. The water used in the Imperial and Royal Sanatorium for Radium Therapy comes from a depth of 900 feet and is said to be the most highly radioactive water known, containing 600 Mache units. This sanatorium was erected in 1911 for the purpose of treating disease with radium salts and also for using the emanations in every known way. The water is prescribed for drinking, bathing and local packing. It is also used to obtain radioactive air for the inhalatorium which is accomplished by forcing air through the water and then into the special room for the inhalation treatment. The sanatorium is complete in its appointments and being under the control of the imperial government will be able to accomplish great good in this special line.

Our other excursion from Carlsbad was to Gieshübeler Sauerbrunn, or Mattoni's Gieshubler, which is said to be six and one half miles from Carlsbad. If our observations did not err, we made the trip in a driving rain by special autos, in thirteen minutes. Even though we exceeded the speed limit, the pelting raindrops never missed a
chance to strike—in fact, at times they reminded one of some electrotherapeutic enthusiast shooting jump sparks at our faces. We even tried to sleep, but an extra dash of speed or rain, now and then, would cause us to scan the horizon for a possible Gatling gun operator who might be practising with fine bird shot. Some of our party did sleep on the return trip, but the rain had ceased then. The immense plant consisting of the springs, the bottling houses, the bath house and the park etc., is owned by the brothers Mattoni. The four springs, though of the same composition, vary slightly in proportions. The principal ingredients are the bicarbonates of sodium and calcium and free carbonic acid; they also possess radioactivity. The water, very pleasant and agreeable to the taste, is shipped for drinking purposes to every civilized country. The enormous bottling facilities enable the owners to export 14,000,000 bottles annually. There is an excellent bath house in which the natural spring water is used, great care being taken to conserve the free carbonic acid. There is also an inhalatorium. Beautiful walks on either side of the Eger river which flows through the place, parks, forests, and hills all go to make an ideal spot for recuperation and rejuvenation.

A little over two hours by train from Carlsbad landed us at the oldest spa of Bohemia—Teplitz-Schönau—which is situated in the northern part near the Saxony border. The Celts and Romans rested here to recuperate from their campaigns, as later on did kings and princes of various nations. Austria at frequent intervals for centuries was in the turmoil of war and Teplitz was so famous a place among the soldiers of this and other nations that it became known as the Warriors' Bath. The wounded and diseased soldiers, friends and foes alike, met here on common ground and mingled freely while receiving the benign, soothing, and healing influence of the radioactive waters. Little did they know why these waters were so wonderfully helpful for the relief of the exhausted and wounded. They were content with the fact that relief was almost certain from their use. The water having comparatively little mineral in it might seem less potent than those that are more highly mineralized. Those of us who know the beneficial effects of that kind of thermal waters, which have marked radioactivity, can realize by observation that their healing powers are all that are alleged for them. If reports are accurate, it is proved at every resort we visited that the radioactive inhalatoriums produce the same beneficial results as do the radioactive baths in the same class of cases, hence raising the question as to how much the mineral content alone has to do with the cure after all.

Since the twelfth century history records the happenings of that country pretty completely. Teplitz suffered much devastation in the Hessite wars, also in the Thirty Years' War, which latter originated near this place. From the tower of the medieval Schlossberg castle, situated on a cone shaped mountain adjoining the city from which an unobstructed view is had in all directions, a low mountain range to the north, in Saxony, can be seen where Napoleon first met at least partial de-

feit from the allied forces of Austria, Russia, and Prussia in 1813.

Teplitz-Schönau is now a delightful city of 28,000 inhabitants. Its famous past is dimmed by its modern repute. It is situated in a comparatively broad valley; is beautifully laid out and has ample, well kept parks, which will for all time accord the invalid visitor an opportunity freely to commune with Nature.

There are five thermal springs, one of which, the Urquelle, produces three million litres of water daily at a temperature of 115.7°F. Space will not allow us to enter fully into detail about all of the springs, bath houses, etc. I can but mention the new municipal bathing palaces, the Kaiserin Elisabeth Bad and the Kaiser Bad, and the two owned by Prince Clary-Aldringen, namely the Herrenhaus and the Neubad. The tubs in the Kaiserin Elisabeth Bad are worthy of special mention. They are miniature pools with steps leading down into them, 700 litres of water being used for each bath. The arrangement for the mud baths was also admirable. The tubs were raised from beneath and accurately fitted an opening in the floor of the bath room. The temptation to go on and describe in detail the many admirable features at Teplitz is strong, and were it possible to command the space we should delight in attempting to do full justice to the springs as well as the city and its hospitable people. After leaving TePLITZ THE radical change of scene and the activities of Dresden, Berlin and Frankfurt am Main gave us renewed pleasure and interest in Bad Naunheim upon our arrival there.

Bad Naunheim lies forty minutes to the north of Frankfurt in the Grand Duchy of Hesse. It is situated on the slopes of a spur of the Taunus mountains called Johannisberg, on the summit of which is a view tower. Prior to 1835, the place was known only for its extensive salt works. Since that time the waters have gradually become more and more noted for their curative qualities until to-day they are famed throughout the civilized world. There are three springs or wells from which the water is used for bathing, and six for drinking purposes. The wells for baths are No. vii, at a temperature of 85.8°F.; No. xii, at 93.9°F.; and No. xiv, at 96°F. These wells, bored at different dates, the first in 1838, combined, furnish about 225,000 gallons daily. The analyses show sodium chloride and free carbonic acid to be the chief ingredients with chloride and bicarbonate of calcium next in importance. The six drinking wells contain much less sodium chloride and slightly less carbonic acid, their waters also being shipped extensively for drinking purposes. The water from the three bath springs is conducted to a central fountain for distribution; however, the bath can be supplied directly from any spring without exposure, thanks to their splendid new conduit system, so that the escape of gas is practically nil. Three principal kinds of baths are given with some variations for each: 1. The Sprudel bath, direct from spring with full CO2 strength; 2. the thermal bath, which is the brine bath without the gas; and 3. the thermal Sprudel, with gas partially escaped. The baths are given at about the natural temperature of the water: however, this must be varied to
suit the case and a fineness in this variation in heart cases is essential, as different temperatures produce different effects on the blood pressure. The cases treated are about seventy-five per cent. circulatory, it was stated; added to these are those diseases needing increased elimination. There are nine bath houses practically new, eight of which are arranged around the new Sprudel fountain.

The springs of Homburg are situated in Prussia about one and one half hour to the southwest of Bad Naunheim. They also are situated on a spur of the Taunus range of mountains in such manner as to have protection from the northwest winds. This resort is another one of those that dates back to very early times, probably even further than any we visited. In pre-Roman times the water was used for the extraction of the salt that supplied the festal boards of the inhabitants of that remote day. Whether it was then used for “cures” is not known; however, it is known that the Romans erected bath houses there for the purpose of using the mineral water. Down through the centuries Homburg is of interest historically, and like most of that region frequently changed masters, the result of the force of arms. Finally it fell into the hands of Prussia, which, on January 1, 1873, turned over the ownership of the springs together with a large capital of accumulated Kurpfonds to the town of Homburg. Thus to-day the city of Homburg is the proud owner of the springs, a magnificent Kurhaus that is indeed imperial in its proportions, interior decorations, and furnishings; also connected with the kurhaus is the new kurhaus bad which was completed in 1902, and the Kaiser Wilhelm bad, which is likewise a modern and beautiful building. Both of these bath houses are complete in every detail and contain all of the most up to date adjuncts to modern balneology. The tubs used here are made of brass, which is an innovation, as at other resorts where carbonic acid is a large component of the water, wooden tubs are used. A feature worthy of mention is the unique manner in which the mud bath tubs are handled. When filled and ready for the bath they are run on a truck upon a subfloor underneath the bath room floor and then lifted as at Teplitz into position through an opening in the floor by means of hydraulic pressure. Another tub, filled with clear water for cleansing after the mud bath, stood beside this. These spring waters are all cold and are heated to the proper degree for the bath with little loss of the CO₂ by a steam container underneath the tub, into which the flow of steam is regulated at will. There are ten springs in all, one the Elizabeth, being a natural spring, and the rest drilled wells. The water contains large amounts of sodium chloride, and free and partly combined carbonic acid. They also contain some bicarbonate of calcium and other ingredients in small amounts. Two are rich in iron.

We arrived at the next and last resort visited—Wiesbaden—late at night on our way from Homburg. Wiesbaden is a modern looking, well built city of 110,000 inhabitants. Situated in Prussia on the southernmost spurs of the Taunus range, which is so noted for its numerous and varied spas, it lies near the renowned Rhine, whose course is dotted with historic castles and whose many legends are wont to keep the traveler’s attention spellbound. Here again we meet with evidences of the ancient “Romans who ruled over this country for a period of 300 years at the beginning of the Christian era.” Some specimens of their masonry are preserved to this day, an example being the Römer tower, which is a broad archway of stone in the heart of the city.

Here are twenty-four thermal springs, of which the Kochbrunnen is the largest, having a flow of 380 litres of water a minute, at a temperature of 150.2° F. The water contains about nine parts of solids to the thousand, of which sodium chloride is the chief ingredient, but this is not in sufficient proportion materially to affect the taste, which is quite pleasant. This spring and the Adlerquelle are situated in the centre of the city. The Adlerquelle furnishes the water for the new Kaiser Friedrich Bad, and the Kochbrunnen alone supplies seven bath houses. Several of the springs are privately owned, and all of the principal bath houses are under private ownership except the new Kaiser Friedrich Bad, which was completed and its opening celebrated last March. This bath house was erected by the municipality at a cost of two and one half million marks, and it may very appropriately be said of it that it is the last word in bathhouse construction. The ordinary expressions that one might use in referring to such an institution do not seem adequate. It surpasses the ordinary, it surpasses even the extraordinary, and stands as a monument to the wisdom, pluck, and energy of Wiesbaden’s officials and to the knowledge and skill of its architect, Mr. A. O. Pauly. Beside having every modern method and appliance that might be used in such an institution, it is really a work of art. In its construction the materials used and the color scheme in the decoration and furnishings of each of the three floors for baths are varied so that monotony does not even suggest itself. The bathing facilities are so extensive in this institution that it is possible for 200 persons to bathe at one time. The fourth floor is occupied by a laundry of such proportions that it can care for the linen of the entire institution when in full operation.

The most beautiful kurhaus we saw on our trip was situated here. The large and stately dining room: the music room and the excellent Kurband of sixty-two pieces; the white and gold reception rooms; the reading room with its 350 newspapers and periodicals from all countries are some of its features. The wisdom of providing such a place for entertainment as well as relaxation is laudable in the extreme, for it not only serves its purpose in that way, but the added possibilities of the refining influence of such environment are great.

In all we visited nine different continental spas. Most of them are known in a more or less familiar way by practically every American citizen. Their reputation has been established and their curative qualities proved locally and likewise recognized for many years by the medical profession throughout the world. At least four of these spas were known and used by the Romans, and from the historical knowledge we have of the old Roman and his bath, how he must have revelled in them! The waters of the different resorts vary chemically. The springs at five of the places contained large quanti-
ties of CO₂, and of these five, three were highly mineralized. At four resorts the waters were cold, at two warm, and at three hot. Five were situated in Bohemia, three in Germany, one in lower Austria. Leaving out Joachimstal there were nineteen-one separate springs from which flowed medicinal waters direct from Nature's own laboratory, and thanks to the enlightenment of the present age, they are being used by people from every clime.

We are glad to note that there is governmental control, either municipal, ducal, or national, at every resort we visited, also that these governments are aiding in every way to advance the scientific knowledge of these spas and their therapeutic use, as well as to popularize them among the people.

**DUGAN-STUART BUILDING.**

ACROMIAL BREATHING AS AN AID IN THE DIAGNOSIS OF APICAL PULMONARY TUBERCULOSIS.

By Nathan Magida, M. D., New York.

It is of the greatest importance to be able to make a diagnosis of pulmonary tuberculosis in its incipiency. We have many signs which help us; the subject, however, being so important, it seems to me that we cannot have too many. The general signs in use at the present time are the prolonged expiratory note, increased whispered sound, dullness and tactile fremitus. Symptoms are of value, especially such as evening rise of temperature, night sweats, weakness extending over some length of time, loss of appetite, loss of weight, and the presence of cough.

Some authorities aver that it is possible to make a diagnosis of tuberculosis by the presence of any one or two of the following signs: Increased whispered sound or dullness on percussion, or increased expiratory sound. The normal differences between the right and left apices should be considered; for instance, the right apex normally presents bronchovesicular breathing in contradistinction to the vesicular breathing of the left apex. Whispered sounds are heard quite plainly over the right apex, but are just audible at the left apex, and on percussion the right apex gives a dull, the left a vesicular, note.

Some time ago, Dr. Robert Abrahams¹ observed that in apical tuberculosis, auscultation at the acromion process increases and amplifies all the auscultatory signs which are ordinarily obtained over the apices. Since then, work has been carried on in the medical clinic of the Post-Graduate Hospital with the result that in almost every case of incipient, and second stage tuberculosis involving the apices, this sign was elicited. In third stage cases, it is rarely found, but of course, such cases can easily be diagnosed without the aid of any special sign.

**Technic.** The hard rubber bell should be used. It is placed over the acromion process of the sca-

¹Abrahams: Auscultation at the Acromion Process: Its Significance in Apical Disease, Archives of Diagnosis, April, 1913.

pula, where it joins the acromion end of the clavicle. Here we are confronted with a slight difficulty in some cases. In thin people this anatomical part is not well covered with muscle and it is sometimes hard to place the bell of the stethoscope in such a manner as to exclude all external sounds. This, however, is overcome by pinching the skin up so that the bone fills the bell of the stethoscope; the surrounding folds of the skin act as a barrier to foreign sounds. Joint breakings which are sometimes heard are easy to distinguish from rales. The value of this method is best appreciated if the apices are examined first, the acromion after, and then the difference in the sounds compared.

Following are a few instances of the average cases of tuberculosis seen daily at the Post-Graduate Hospital medical clinic, showing the presence or absence of acromial breathing:

**Case I.** P. S., male, aged twenty-one years, had been complaining of weakness for the last two or three months, had lost his appetite, could not do his work properly, was very warm toward evening and perspired a good deal when in bed. Did not complain of any cough. On examining this man, we found:

Left apex marked bronchovesicular breathing and increased whispered sound. No rales. Acromion process, prolonged expiratory note and whispered sounds greatly increased. The percussion notes over the left and right apices were found to be the same, showing the left apex dulled. The right apex was normal. A diagnosis was made of incipient tuberculosis, left apex.

**Case II.** D. S., male, aged thirty-two years, complained of indigestion and weakness; after nearly every meal complained of feeling "blown up." Had sour taste in mouth, and sometimes regurgitated small amounts of food. Complained of frequent headaches, and chills.

Left apex showed on auscultation, marked prolonged expiratory note; mucus click at end of inspiration; whispered sound heard very distinctly. At the acromion process, these sounds were heard much more distinctly, rendering the breathing almost tubular and the whispered sound almost pectoriloquy. Percussion was dull. The right apex was negative. The diagnosis was first stage tuberculosis, left apex.

**Case III.** A. C., female, aged thirty-eight years, had been complaining for the last three years of cough, followed very frequently by expectoration, which was becoming more and more distressing; marked weakness; had had two hemorrhages. Upon examination, right and left apices were found to be involved.

Left apex showed bronchial breathing, coarse rales, both on inspiration and expiration. Whiskered sounds markedly increased. At the acromion process, no sounds were heard. Percussion was dull; palpation gave tactile fremitus. At the right apex were bronchial breathing, loud whiskered sounds, rales on inspiration and expiration; at the acromion process, nothing was heard. Percussion was almost flat, while palpation gave tactile fremitus. The diagnosis was third stage tuberculosis, both apices.

**Case IV.** C. E., male, aged thirty-four years, complained of cough and expectoration for last year. During the last month had noticed streak of blood at times in the expectoration. Felt weak and could not do his work, complained of feeling chilly frequently.

Left apex gave prolonged expiration, increased whispered sounds, mucous rales at end of inspiration. At the acromion process, all sounds were enormously amplified. Percussion was dull, palpation gave tactile fremitus. The right apex was negative. The diagnosis was second stage tuberculosis, left apex.

**Case V.** B. F., female, aged thirty-two years, for last two and one half years had been complaining of cough followed by expectoration, which at times was streaked with blood. Within last year had had two small hemorrhages. Felt very weak and could not do her housework. Upon examination, left and right apices were found to be involved. Left apex showed bronchovesicular breathing, increased whispered sounds, fine rales at end of inspiration. At
acromion process, no sounds heard. Percussion was dull; palpation gave tactile fremitus. Right apex showed bronchial breathing, mucous rales on inspiration and expiration, whispered sounds greatly exaggerated. At acromion process, no sounds. Percussion was almost flat, palpation gave tactile fremitus. The diagnosis was second stage tuberculosis, both apices.

Case VI, S. F., female, aged twenty-two years, for last two and one half years had been complaining of cough followed by expectoration, which at times was bloody. Had had three hemorrhages. Very weak; frequent night sweats and steady emaciation. Right and left apices involved.

Left apex showed bronchovesicular breathing, marked increased whispered sounds. Rales on inspiration and expiration. At the acromion process, was marked exaggeration of all sounds. Percussion was dull; palpation gave tactile fremitus. Right apex exhibited bronchial breathing, marked increased whispered sounds, loud rales on inspiration and expiration. Signs at the acromion process were negative. Percussion was flat; palpation gave tactile fremitus. The diagnosis was advanced second stage tuberculosis, left apex; third stage, right apex.

CONCLUSIONS.

In looking over the histories of fifty-two cases, consisting of twenty-eight in the first stage, fourteen in the second, and ten in the third, we found acromial breathing present in all the first stage cases, in eight of the second and two of the third. It would seem that it is a valuable method in first stage cases, and since that stage is the most important from a diagnostic point of view, and as the method is so easily acquired, it should be universally employed. It should also help toward ascertaining the advanced stages of tuberculosis, as the further advanced a case is, the less probability there is of getting evidence from auscultation of the acromion process.

A short trial will convince anybody of the merit of this method and will conclude with its originator that the subject deserves a place in physical diagnosis.

THE ETIOLOGY OF PELLAGRA.

A Review of Recent Theories.

By Paul Bartholow, A. B., M. D., New York.

Under the title, The Etiology of Pellagra, Perroncito (Sperimentale, supplemento al fascicolo, iv, September, 1913) has put in very plain and simple language a very complex and difficult conception; that of pellagra. He succeeds admirably; we are brought appreciably nearer to the nature of the disease, yet the final cause continues to elude our grasp.

To explain the etiology of pellagra, Perroncito institutes a careful comparison between three prominent theories—the zeistic, the toxic-zeistic, and the parasitic. The zeistic theory is the product of the school of Strambio and Lussana, which tried to connect pellagra with the habitual and almost exclusive eating of Zea mais or Indian corn. Maize, whether sound or not, without the addition (correttivo) of nitrogenous food, is supposed to be an influence in producing the symptoms of pellagra. Maize, as Lo Monaco believes, has no proportion of protein capable of maintaining the nitrogen balance. Accordingly the occurrence of the disease rests upon the fact that there is a deficiency of nervous and muscular nutrition. Such is the theory of Strambio, and its undeniable aspect of truth has fundamentally affected the physician’s notion of pellagra. In Perroncito’s phrase, the present definition of pellagra is, that a maize diet and poverty (miseria) are two elements of great importance; and there is no doubt that spolt maize is toxic.

There are many communities, however, which are poor and which habitually eat maize, yet do not necessarily suffer from pellagra. Even maize spolt by moisture does not always produce it. The effects of spolt maize are undoubtedly evil, but their operation is superficial and frequent, and pellagra is limited to definite regions and often to definite periods of time. Thus the zeistic theory does not explain why pellagra has a distinct periodicity, why it is more common in spring, in the absence of running water, and why relapses occur long after a diet of maize has been given up. Finally, pellagra is found in people who do not eat maize.

Pellagra is something other than the product of the food habitually eaten. The toxic-zeistic theory is thus stated by Lombroso: Pellagra is the effect of an intoxication produced by poisons which are developed in spolt maize by certain microorganisms in themselves harmless. This theory is so grounded in the common consciousness that it is the basis of the Italian legislation on the subject. It is true that the colon bacillus cultivated in maize gives very powerful toxins. If not strictly a coli infection, pellagra may well be connected with it. Maize undigested in the intestine undergoes a putrid decomposition, and, as De Glaxa has pointed out, is admirably adapted for the growth and maintenance of bacteria. In such a medium germ increase both as regards their numbers and their virulence. Maize is also liable to a peculiar fermentation by fungi, Penicillum glaucum being the most common. This unquestionable fact has been carefully developed by Lombroso, following Sette and Balardini, the protagonists of the toxic-zeistic theory. Lombroso began his experiments with this fermented maize, with maize spolt by moisture, and, lastly, with putrid maize. Subsequently he made an extract of putrid maize with alcohol, and administered it to men and animals. Limiting his attention to this toxin, called pellagroseine, he ascribed the origin of the nervous, the gastrointestinal, and cutaneous symptoms to its operation. These conclusions, however, were not countenanced by a commission from the Institute of Lombardy, especially appointed to examine the experimental results. Pellagroseine, it was found, is so feebly toxic that it would require the consumption of ninety kilogrammes to produce a fatal dose. Nor again does this theory, however impressive, and in virtue of which laws are made, explain the existence of pellagra in dry regions, nor its periodicity, nor its frequency near stagnant water.

Another circumstance of importance is the growth of moulds in maize. One of these, almost constantly found and mentioned before, is Penicillum glaucum. Gosio regards this parasite as an essential condition of the spread of pellagra. Another fungus, which produces an infection from
which people die, is aspergillus. According to Ceni, two varieties are found in maize, *Aspergillus fumigatus* and *Aspergillus flavescens*, and the toxin they produce enters the pleura, pericardium, and lungs. It is most probably a phenol, parahydrocumaric acid. Is pellagra a phenol intoxication? Those who expound the photodynamic theory of pellagra are inclined to answer this question in the affirmative. They view these phenols, as well as hemeatoporphyrin, also developed in the metabolism of maize, as sensitizers of the tissues, especially to light. Centanni and Galassi have examined these premises experimentally without definite conclusion in their favor, and it is known that the erythema of pellagra appears not only in winter when the sun's rays are weak, but on covered parts of the body. The eruption also appears when maize has been excluded from the diet. In support of the view, which puts the essential cause of pellagra on the eating of maize, Zuntz asserts that it contains toxic substances, one of which, zeine, is a phenol, and Albertoni contends that as a food it is inadequate and therefore a cause.

The truth is, as Sambon declares, pellagra is not due to either sound or spoilt maize. He lays down several propositions. First, the foci of pellagra are strictly related to streams of running water; secondly, the infecting agent is a parasite conveyed by a bloodsucking fly, probably *Simulium*. *Simulium* has, in fact, the same geographical distribution. On the other hand, Alessandri conjectures that the infecting agent exists in stagnant water, that it has no intermediate host, that most probably it is a species of filaria. This theory deserves careful attention. Filariasis would explain many phenomena of pellagra, e.g., the periodicity, its epidemiology, the intervals of latency, and the erythema. But filaria is an obligatory parasite, at least as far as we are aware, and must have an intermediate host. The question concerning filariasis cannot be answered until it is determined exactly what the nature of this parasite is. The fact is obvious, however, that the parasitic theory is gaining ground.

Tizzoni isolated a microorganism which he believed to be the cause—a pleomorphic bacillus. Later, as his results were not confirmed by Perroncito, Bezzola, nor Raubitscheck, he considered his bacillus as a pleomorphic type of actinomycte. Among biological evidences are the facts mentioned by Lombroso; that the serum in pellagra is toxic, that patients show anaphylaxis to putrid maize, and disorders of the sympathetic and cerebrospinal nervous systems, but precipitins and deviation of complement have not been demonstrated.

In conclusion, Perroncito is profoundly impressed with the connection of causes and effects. One of these is certainly spoilt maize. Another, not to be ignored, is the economic condition that leads us to distinguish accidental concomitants from essential conditions. We have in pellagra a fixed and somewhat circumscribed disease, connected in a manner still unknown with spoilt maize, with poverty, with malnutrition, possibly with parasites and insects living near stagnant water, but with no one cause exclusively nor universally. Pellagra implies a state which is the very antithesis of the economic and hygienic spirit, and this truth is a grand compensation for the inability to discover the other causes.

**THE TREATMENT OF BRONCHOPNEUMONIA IN CHILDREN.**

By Abraham Goltman, M.D., New York.

So much has been written on this subject—the newest drugs, theories, and treatment—that after one tries them all one comes to the conclusion that one, and only one, essential treatment will pull the little patient through, and that is good nursing.

Pneumonia cannot be cut short by drugs, and too much medication is poor treatment as well as dangerous. I have had occasion to see a tired out heart whipped up with stimulants, and one wonders, in fatal cases, whether the heart gave out from the disease itself or from the cardiac stimulants.

In a severe case of bronchopneumonia, a child's recovery or death will, in a good many cases, bear some relation to the surrounding hygienic conditions, previous condition of health, and the causation—in other words, whether secondary to some of the infectious diseases or not.

Support the patient's strength with nourishing liquid diet, and let the temperature and pulse be your guides as to whether you should use stimulants. The ice pack will reduce a temperature in quick time. When mucous rattling is heard, when the respirations are increased and dyspnàea and cyanosis are present, aim at one thing—keep the respiratory centre alive. Plunging the child into a warm bath and then wrapping it up in a cold sheet, pouring hot and cold water alternately from a height on the patient's chest will cause the child to cough and expel the mucus.

These seem heroic measures, but I reported a case in the *New York Medical Journal*, some time ago, where death was imminent and these measures were tried with good results. By adopting them, instead of waiting for the uncertain results of medication, good results will ensue.

**895 Kelly Street, Bronx.**

**Pituitary Extract in Threatened Mammary Abscess.**—J. A. Henton White, in the *Practitioner* for September, 1913, states that while the employment of pituitary extract in the condition mentioned is not commonly thought of, experience leads him to consider the drug very useful. It has been experimentally shown that within a few minutes after the injection of pituitary extract the flow of milk is much increased, owing to contraction of the muscular fibres of the lacteal duct walls. When these ducts contain pus and are blocked, this action is a useful one, and in two or three instances the author has found a threatened abscess to undergo absorption soon after giving pituitary extract.
PRIZE ESSAYS.

Questions for discussion in this department are announced at frequent intervals. So far as they have been decided upon, the further questions are as follows:

CXL. How do you treat frostbite? (Closed.)

CXLII. How do you treat chronic constipation? (Answers due not later than January 15, 1914.)

CXLIII. How do you treat gallsone colic? (Answers due not later than February 16, 1914.)

Whoever answers one of these questions in the manner most satisfactory to the editor and his advisers will receive a prize of $25. No importance whatever will be attached to literary style, but the award will be based solely on the value of the substance of the answer. It is requested (but not required) that the answers be short, if practicable no one answer to contain more than six hundred words; and our friends are urged to write on one side of the paper only.

All persons will be entitled to compete for the prize whether subscribers or not. This prize will not be awarded to any one person more than once within one year. Every answer must be accompanied by the writer's full name and address, both of which we must be at liberty to publish. All papers contributed become the property of the Journal. Our readers are asked to suggest topics for discussion.

The Prize of $25 for the best essay submitted in answer to Question CXXXIX was awarded to Dr. J. Walker Moore, of Philadelphia, Pa., whose article appeared on page 1117.

PRIZE QUESTION NO. CXXXIX.

TREATMENT OF CHANCROIDS.

(Concluded from page 1221.)

Dr. H. S. Holloway, of Jacksonville, Fla., says:

I have found nothing so thoroughly satisfactory in meeting all the foregoing requirements as the powerful escharotic, acid nitrate of mercury. This medicament possesses unusually great penetrating properties, and is a notable stimulant in promoting absorption of broken down tissue. When I am called upon to treat a chancroid, I first wipe dry the surface of the ulcer with sterile absorbent cotton. Then with a pledget of cotton saturated with hydrogen dioxide I reanoe the surface, drying as before. Now, with a fine pointed toothpick upon which a fine film of cotton is twisted, I dip it into the acid nitrate of mercury, exercising care to avoid supersaturation, and lightly touch the entire surface of the ulcer until it appears of a whitish color. If the ulcer is unusually sensitive, I first touch it with a ten per cent. solution of cocaine.

When the chancroid presents an ugly greenish hue with a tendency to phagedena I use the Paquelin cantharid and very lightly touch the margin of the sore.

Following the cauterizing process, I first remove any moisture that may have accumulated, then, thoroughly dust the sore with bismuth formic iodide, apply a compress of sterile gauze or cotton and bandage the penis, cautioning the patient not to remove the dressing, and not to let it become wet.

The second day, I cleanse the wound as at first, and if after thoroughly washing the surface of the sore the exudate has not all come away, I recauterize these areas, always doing a punctate cauterization, avoiding a too drastic use of the drug.

I dress the wound as at first and repeat this process once daily, providing the patient is convenient to my office, until the chancroid presents a red, clean, granulating surface, and as soon as this condition is attained I discontinue the routine application of the cauterizing agent, using it only when the wound shows a tendency to relapse into a sluggish state of healing. In place of bismuth formic iodide, iodiform may be used as a dusting powder. Iodoform has no antiseptic property in its pure state but in the presence of pus disintegration takes place with the formation of substances inhibitory to germ growth. I have seen iodiform set up a dermatitis medicamentosa and cause undue damage. I have never seen any untoward effects from bismuth formic iodide.

To prevent autoinoculation of the sore, which is very apt to occur unless one be very careful to keep the infectious secretions away from healthy tissues, I keep the ulcer very dry and after dressing the sore, I wipe the surrounding skin with a one in 3,000 solution of bichloride of mercury.

Not infrequently one encounters chancroid complicated with phimosis. Here, if the phimosis cannot be relieved by ordinary measures, the foreskin should be slit over the dorsum of the penis sufficiently to expose the ulcers and permit the underlying parts to be thoroughly cleansed. If the chancroid is situated on the foreskin, and the foreskin is unduly long, and the patient is willing, circumcision may be resorted to, thus accomplishing two purposes at the same time.

When the chancroid is situated in the urethra, as sometimes happens, the secretion ought to be examined microscopically to differentiate it from gonorrhea and if found to be chancroid, irrigation should be resorted to and if the sore is situated some distance from the meatus it is best to use the urethroscope, cauterizing it at the same time.

In doing a circumcision on a chancroid patient, one must be particularly careful to avoid contaminating the knife, thus running the risk of setting up multiple chancroids.

When the phimosis is attended with considerable edema, I merely slit the foreskin over the dorsum, sewing up the inner and outer skin on each side, until the edema subsides, when a circumcision can be done if desired by the patient.

Usually, if the chancroid is kept clean and properly cauterized, the tendency to bubo formation in the groin will be avoided. When buboes have already formed, but are yet in the early stage, a very firm compress over them with a tight bandage often does good, at the same time painting the skin over affected side with tincture of iodine or colloidal silver. The bowels should be kept open and the urine kept bland by the administration of infusion of digitalis or bucht.1
A very useful preparation to apply locally is the following:

R Untg. hydrargyri, ......} Untg. iodii comp., ......} Untg. belladonne, Untg. petrolatii carbolati.

Sig.: Apply locally twice daily.

When suppuration has occurred or is inevitable, as evidenced by fever, sweats, and a fluctuating mass in the groin, free evacuation is the best treatment. Remove all pus, and glands too, if possible, then pack the cavity with iodiform gauze and permit the ulcer to heal by granulation.

Sometimes a sore will not heal but continues ugly and may even become more dangerous. Here one must ever keep in mind the possibility of chancre and chancreoid in the same site. I encountered such a case and was profoundly puzzled until the administration of mercury caused a graduated disappearance of the sore, but the glands of the groin suppurated and Treponema pallidum was found in the serum from the sore. In other cases when a chancreoid fails to heal, the general health should be looked into. Evidence of tuberculosis, syphilis, scrofula, etc., should be looked for and if found should be properly treated. Tonics of a ferruginous type may always be given and they seem to do good. I always advise patient to drink plenty of water, to keep the bowels freely evacuated, and to avoid all irritating foods. Meats had better be withheld. All vegetables are allowed.

Cleanness, after all, is sine qua non in treating all cases of chancreoid. Effort should also be made to keep the parts dry. Some recommend the complete extirpation of the chancreoid when seen very early before much tissue is involved. I have never been successful with this treatment.

The bacterin treatment may be tried. Personally, this treatment in my hands has been eminently unsatisfactory.

**Therapeutic Notes.**

**Local Use of Ether in General Peritonitis.**—Patel, in Lyon médical for October 26, 1913, reports the case of a woman fifty-seven years of age, seriously ill with general peritonitis apparently of appendicular origin, in whom incision (thirty-eight hours after the onset of peritoneal symptoms) revealed a normal appendix but perforation of the ileum about ten inches from the ileocecal valve. Fluid with a fœcal odor welled up from all parts of the peritoneal cavity and there were no adhesions. The perforated loop of gut was brought up, after drying the peritoneum as thoroughly as practicable, 150 to 200 c. c. (five to six and one half ounces) of ether poured into the abdomen, and the incision partly closed, leaving the perforated loop outside the wound. Within a few hours a remarkable degree of improvement was noted, the patient feeling well and color returning to her skin. One pint of saline solution was the only additional measure instituted. Eleven days later, the patient being in good condition, unilateral exclusion of the ileum was performed, with ileosigmoidostomy, to be followed later by excision of the involved gut. The author considers the perforation in this case to have been of tuberculous origin. While direct drainage of the gut undoubtedly proved beneficial, Patel believes the ether to have been responsible for the surprisingly prompt and marked improvement in the patient's condition. In two cases of less extensive peritonitis—one in a young patient with double pyosalpinx and pus up to the level of the umbilicus, and the other in a woman of sixty, with malignant ovarian tumor—pouring 150 c. c. (five ounces) of ether into the peritoneal cavity produced a striking tonic effect. In each of the three cases the pulse frequency increased for five to ten minutes after the introduction of the ether; then the pulse became slower and of good volume. The postanesthetic period of sleep was prolonged about two hours by the measure, and at the moment of awakening the tonic influence of the ether became clearly manifest, continuing, moreover, on the succeeding days. The ether flows rapidly in all directions when introduced into the peritoneum, and its antiseptic effect is evidently exerted over a wide area—much better than with camphorated oil. Ether poured into the abdomen of unanesthetized patients was found not to cause pain; as usual, the pulse frequency increased for a few minutes, then rapidly improved. The contact of ether with the intestine causes it to redder and contract. In short, further trial of ether in grave peritonitis seems desirable.

**Treatment of Pruritus ani.**—Jerome Wagner, in the International Journal of Surgery for March, 1913, warns that in patients complaining of itching about the anus one should not rest content with prescribing, but should examine the part, look into the rectum, and likewise ascertain if any constitutional derangement is present. Limitation of the diet will often relieve a previously most persistent pruritus.

As proctitis is nearly always associated, cleansing irrigations are indicated. A two per cent. hydrogen dioxide solution is excellent for this purpose. From two to four quarts should be used morning and night.

To procure temporary relief from the itching, local applications containing calamine or tar are very efficient. One may prescribe, for example:

R Calamin., { Zincii oxi., ..........} Glycerini., Liquoris calcis, q. s. ad.}. Fiat pulvis.

If the perineal skin is moist, a warm sitz bath, followed by a dusting with:

R Zincii oxi., Hydargyri chlorid mitis, ..........} Amyll., Fiat pulvis.

will afford relief.

Pediculi and pinworms should not be overlooked as possible causes of pruritus. The former can be overcome with mercurial ointments; the latter, by injections of lime water or of:

R Quassiae, ..........} Aquae Bulliiatur, Fiat injectio.

In cases of anal pruritus of marked chronicity and severity, radical operation alone permits of relief.
CAUTERIZATION IN THE TREATMENT
OF INOPERABLE UTERINE CANCER.

Early diagnosis of uterine cancer is, obviously, of major importance to enhance the chances of operative and permanent recovery. Unfortunately, inoperable cases constitute the larger group, owing either to delay on the part of the patient to apply for treatment or to tardy recognition of the true nature of the disease. That this large proportion of cases is not to be ignored, however, is self evident; indeed, our resources having for their purpose to delay the development of the growth are steadily increasing, and a few methods are so useful in this direction that at times they initiate convalescence or at least restore previously doomed patients to the operative field. Even advanced cases of inoperable uterine cancer are susceptible of temporary improvement, as illustrated by the results of extensive cauterization of the cancerous mass noted by many surgeons. In a clinical study of this important question, Howard A. Kelly and J. Craig Neel (Johns Hopkins Hospital Bulletin, December, 1913) emphasize the value of such a procedure.

Decreased mobility of the diseased cervix is generally considered the most important factor in determining whether or not the extensive operation required in these cases is advisable. But Kundrat showed, ten years ago, that the induration could be due to a secondary inflammatory process rather than to carcinomatous infiltration. Again, decreased cervical mobility may be due to extension of the growth to both broad ligaments; to infection of the carcinomatous mass through the presence of inflammation in these ligaments or of an extensive pelvic peritonitis involving them. To determine just when a cervical cancer is actually inoperable, therefore, is often very difficult without an exploratory operation. This procedure enabled Aulhorn to redeem forty-two cases out of 221 apparently inoperable ones.

Kelly and Neel summarize their clinical study of the subject as follows: The extensive radical abdominal operation offers the greatest hope of absolute cure in patients suffering from carcinoma of the cervix of the uterus. The percentage of operability has gradually increased with the adoption of the radical abdominal operation. An exploratory operation is occasionally necessary to determine whether or not the radical operation is to be attempted. Immobility of the cervix is not an infallible sign in determining whether or not a case is operable.

As to the use of the cautery, they conclude that in advanced cases of carcinoma of the cervix a preliminary curettage and cauterization is advisable, for the following reasons: A large portion of the friable new growth may be removed through the vagina. The curettage and cauterization constitute an important procedure in the disinfection of the vaginal field. The induration in the broad ligaments, due to secondary inflammatory reaction, may be relieved, causing the new growth to become circumscribed and rendering mobile a cervix previously immobile.

ONE PROBLEM IN GYNECOLOGY.

It has become a truism that each case of disease presents an individual problem, a prominent factor in the symptom complex being the patient’s self. While the practitioner may be armed with the most precise information from the laboratory and have gained a perfect concept of the physical conditions present by thorough and competent use of his eyes, ears, and fingers, there still remains, particularly if the physician is a gynecologist, the most disturbing and baffling equation of the whole calculation—the individual woman. The higher in the social scale she is, the more elusive is her personality. There
The Diagnosis of Rabies.

How far is the parasitic theory suited to the right diagnosis and classification of the cell inclusions of Ammon’s horn called the Negri bodies? The old problem is taken up by Dr. Lina Negri-Luzzani in a striking article contributed to Pathologica, v., p. 253. 1013. The subject is clearly defined in the title, the diagnosis of rabies with the demonstration of the specific parasite. The specific parasite, in a word, is the Negri body, and the paper frankly sets out to justify this proposition.

Accordingly, Doctor Luzzani deals with a specific parasite, or at least with specific forms, concerning herself mainly with the question, how far ultimate authority for this belief should depend upon the morphology of the Negri bodies and the frequency with which they are found in rabid animals. The best specimens, fully developed, are seen in Ammon’s horn, but smaller types occur in the cortex, the medulla, and spinal ganglia, even the Gansserian ganglion. In a series of 1,650 animals, Doctor Luzzani found them in 1,605. This corresponds to the world estimation of these bodies. They are essential to the diagnosis of rabies. But what is to be made of the eosinophile granules, of spherical form, occurring in the protoplasm of the nerve cells? These are found in other diseases, in tetanus, in pyocyanus poisoning, in poisoning with snake venom and arsenic. Whatever experts may ultimately decide with still fuller knowledge, it is clear that these granules are highly significant; but their parasitic nature, if they have any, appears to be unsettled.

Thus on the main question the article is decisive. The Negri bodies are certainly diagnostic, and the tone and balance of the paper insist strongly on their parasitic nature. It brings the subject to the centre of all that interests most in the characters of these bodies, especially the side which so nearly concerns their possible protozoan origin. The points that strike us most about them—why they are found equally in all animals that can become rabid, why the furious form furnishes the most perfect specimens in Ammon’s horn, why they are different in different species, and in fixed and street virus infection—require to be answered on a plan which may be called physiological if not ontological. The alternative is strongly presented: “Are the Negri bodies the expression of a stage of evolution of a living existence (esser vivente), or do they represent a reaction of the nerve cell to a hypo-
tethical parasite within themselves, or again a re-
action of the nerve cell to the rabic virus? In any
case they constitute a specific existence.” We may
freely confess that the parasitic nature of the Negri
bodies is not more remarkable than the uniformity
with which they occur in rabies. If they are not
parasites, or related to parasites, what are they?
Opinion tends to connect them with the parasitic
class.

THE INTRAMUSCULAR INJECTION OF
SALVARSAN AND NEO SALVARSAN.

Unquestionably in this country, and probably also
abroad, the method of choice for the administration
of both salvarsan and neosalvarsan, and the one
in general use, is that by intravenous injection.
Among the chief objections which have been found
to intramuscular injection is its painfulness; Dr.
W. S. Gotthiel, in a paper published in this Journal
for June 7, 1913, asserts that it is not only less
desirable, but less effective than the intravenous
route. Last winter, at a meeting of the Medical
Association of the Greater City of New York,
Dr. A. L. Wolbarst stated that in a conversation
which he had had some months previously with
Professor Ehrlich, the latter had expressed the
view that if a painless plan for performing it
could be devised, intramuscular injection would
eventually become the only method used for
the administration of salvarsan and neosalvarsan.
He (Doctor Wolbarst) then went on to describe
the efforts he had made in this direction, and said
that these had proved successful to the extent that
from seventy to ninety per cent. of the injections
were comparatively painless.

On the other hand, Dr. H. E. Robertson, associ-
ate professor of pathology in the School of Medi-
cine, University of Minnesota, as the result of the
observations of K. Martius, Busche, Wise, Swift,
and Tomasczewski, and of two series of experi-
mental investigations on animals by himself, to-
gether with two cases in human beings which came
to necropsy, arrives at the conclusion (Journal of
the American Medical Association, November 8,
1913) that the intramuscular injection is certainly,
in the majority of instances, an unjustifiable
procedure. His own work, he states, was carried
on for the purpose of making intensive studies
of the peculiar type of necrosis noted by others
and of observing, 1, the effects of salvarsan
on the muscles of animals compared with its
effects on the muscles of human beings; 2, the
effects of salvarsan compared with those of neo-
salvarsan; and, 3, the effects of both these drugs
compared with those produced by deep in-
jections of the mercurial preparations more com-
monly employed in the treatment of syphilis. The
animals made use of in his experiments were dogs,
and in the first series, of thirty animals, salvarsan
and neosalvarsan were given intramuscularly.
Among the results observed in these cases were
the following: The lesion consisted of hemorrhage
and necrosis, with edema which developed almost
immediately after the injection; leucocytes early
invaded the tissue and tended to form a zone around
the necrotic area; there was no appreciable differ-
ence between the severity of the lesions appearing
after the injection of salvarsan and of neosalvarsan;
no changes in the general health of the animal
could be observed, and there was no evidence of
any marked tenderness at the site of the injections.
In the second series, of twelve animals, mercurials
were employed by intramuscular injection, and the
reaction was similar, at least in its early stages,
to that obtained with the arsenical drugs, al-
though the results did not appear to be so severe.
Robertson bases his conclusion as to the unjusti-
fiability of the intramuscular injection of salvarsan
and neosalvarsan, as well as of mercurials, on the
facts observed by him that all these drugs, admin-
istered in this way, uniformly produce destructive
lesions which always heal slowly and are often
complicated by hemorrhages and sloughing ab-
scesses, while salvarsan invariably leaves an in-
soluble pigment which acts as a foreign body.
Many syphilographers, however, who prefer the in-
travenous method for salvarsan, are constantly giv-
ing full doses of mercury by intramuscular injec-
tion, and apparently do not meet with the dele-
tious results which Robertson describes.

SPIROCHETA PALLIDA IN LATE SYPH-
ILIS.

Since the discovery of the spirochete in the gray
substance in general paralysis and in tabes, another
curious question has arisen, How often is the para-
site to be found in other instances of late syphilis
—of the heart, vessels, liver, kidneys, spleen, and
glands? According to Chiefi, in Giornale interna-
tionale delle scienze mediche for November 30,
1913, its presence could not be traced in the very nu-
merous specimens which he examined. He measures
the difficulty of the task, when he was unable to find
genuine spirochetes in cases of general paralysis,
and even in syphilis of the arteries, liver, and
spleen. In strong contrast is the frequency of
finds in congenital syphilis. While he casts no
doubt on the positive results of other authors, it
does not follow so conclusively as some suppose
that Spirocheta pallida is always to be found in the
organs of late syphilis. He found it in none,
though he used smears stained by Levaditi’s and
Giemsa’s methods.
Smallpox in Niagara Falls.—Acting Assistant Surgeon Bingham, of the United States Public Health Service, stationed at Niagara Falls, N. Y., reported eleven cases of smallpox in that city during the week ending December 13th.

Meetings of Medical Societies to Be Held in Philadelphia during the Coming Week.—Thursday, January 1st, Obstetrical Society; Friday, January 2nd, Kensington and Southeast Branches of the Philadelphia County Society.

Philadelphia County Medical Society.—The Kensington Branch of this society has elected the following officers to serve for the year 1914: Vice-president, Dr. Edwin Thorne, of Haddonfield, N. J.; secretary, Dr. William Dempsey; clerk, Dr. Harvey W. Gooss; chairman of committee on programme, Dr. John F. Roderer.

Genitourinary Clinics at the West Side German Hospital.—Dr. A. W. Lobbars will hold a genitourinary clinic on Thursday evenings at 8:30 o'clock, from January to May, inclusive, at the West Side German Dispensary and Hospital (New York School of Clinical Medicine). These clinics will be free to physicians.

Tri-State Medical Society.—At the tenth annual meeting of the Tri-State Medical Society of Arkansas, Louisiana, and Texas, held in Texarkana, Texas, on Tuesday and Wednesday, December 9th and 10th, Dr. Preston Hunt, of Texarkana, was elected president for the ensuing year, and Dr. R. E. Rock, of Alexandria, was elected vice-president for Arkansas; Dr. J. E. Kingston, of Shreveport, for Louisiana, and Dr. Thomas J. Allison, of Redwater, for Texas. Dr. J. M. Bodenheimer, of Shreveport, was re-elected for the sixth time as secretary.

Personal.—It is reported that Dr. Livingston Farrand, professor of anthropology at Columbia University, has accepted the presidency of the University of Colorado.

Dr. J. H. Comstock, professor of entomology at Cornell University, will retire at the end of the present academic year.

The Nobel prizes in physics and chemistry have been awarded to Professor H. K. Onnes, of the University of London, and Professor Alfred Werner, of the University of Zürich, respectively.

North Texas Medical Association.—The sixty-eighth semiannual meeting of this association was held in Fort Worth on Tuesday and Wednesday, December 9th and 10th, under the presidency of Dr. M. E. Taher, of Dallas. Dr. K. H. Beall, of Fort Worth, was elected president to serve for the ensuing year, and Dr. J. D. Burt, of Farmerville, vice-president. Dr. H. Leslie Moore, of Dallas, was re-elected secretary, and Dr. Willard Fisk, of Lancaster, was elected treasurer. The next semiannual meeting of the association will be held in Gainesville.

Trichinosis to Be Reported.—At a meeting of the Department of Health of the City of New York, held on December 9th, the following resolution was adopted:

WHEREAS, Trichinosis, a very painful disease occasionally followed by death, is caused by eating meat, especially pork, which has been invaded by Trichinella spiralis and has not been sufficiently cooked to destroy this worm, which causes trichinosis, therefore be it

Resolved, That the department of health requires all physicians to report cases of human trichinosis.

To Regulate the Work of Dispensaries.—At a recent meeting of the County Medical Society recommendations were adopted for the regulation of the work of dispensaries. These institutions should be operated exclusively for the benefit of the poor who are unable to pay for advice and medicine, and it was suggested that the practice of exacting a small fee for medicine should be abolished. The society also recommended that the board be divided into districts and that prospective patients should be compelled to call at the dispensary in the district in which they live, exceptions to be made in special cases. Finally, the recommendation of the society commends the discontinuance of the practice by which certain physicians have a monopoly in constituting the medical and surgical staffs of these institutions. This is contrary to the medical law which gives the opportunity to practise in these institutions, so they may extend their knowledge in medicine and surgery. All these recommendations by the medical society have the endorsement of the State Board of Charities.

Medical Society of the County of Kings, N. Y.—At the ninety-third annual meeting of this society, held on Tuesday evening, December 16th, Dr. J. Richard Keen was unanimously elected president. The officers elected were: Vice-president, Dr. Russell S. Fowler; secretary, Dr. Burton Harris; associate secretary, Dr. Charles E. Schofield; treasurer, Dr. Stephen H. Luce; associate treasurer, Dr. Robert L. Moorhead; directing librarian, Dr. Frances A. Tilney; and James J. McKee, vice-president.

Richmond, Va., Academy of Medicine and Surgery.—Dr. Charles V. Carrington was elected president of this organization, at the annual meeting held on the evening of December 9th. Other officers were elected as follows: vice-president, Dr. W. W. Penfield; second vice-president, Dr. Thomas W. Murrell; third vice-president, Dr. J. Fulmer Bright; secretary for the twenty-first year, Dr. Mark W. Peyer; assistant secretary, Dr. E. H. Terrell; treasurer, Dr. W. A. Shephard; librarian, Dr. G. F. LaRoque; judiciary committee, Dr. Clifton M. Miller, Dr. Moses D. Hoge, Dr. H. H. Levy, Dr. McGuire Newton, Dr. Robert C. Bryan, and Dr. A. L. Gray. Dr. Charles L. Brock was elected to membership.

Children's Hospital of Virginia and North Carolina.—At the closing session of the eighteenth annual convention of this society, held in Norfolk, Va., on Thursday, December 11th, the following officers were elected to serve for the ensuing year: President, Dr. W. H. Parker, of Goldsboro, N. C.; vice-president, Dr. G. K. Vandervisler, of Phoebeus, Va.; second vice-president, Dr. C. F. Griffin, of Winton, N. C.; third vice-president, Dr. R. E. Whitehead, of Kempsville, Va.; fourth vice-president, Dr. W. J. Harrell, of Elyria, Ohio; treasurer, Dr. Clarence Porter Jones, of Newport News; secretary, Dr. George A. Caton, of New Bern, N. C.; orator, Dr. James H. Culpepper, of Norfolk. Next year's meeting will be held in Goldsboro, N. C.

Gifts and Bequests to Hospitals.—By the will of Mrs. Emma Hayray Rayford, daughter of the late Dr. E. E. Marcy, the Hahnemann Hospital, New York, will receive, on the death of the life beneficiaries of the income, the proceeds from the sale of property valued at about $300,000.

Philadelphia Hospital and Homeopathic Hospital have received $7,500 for the purchase of a free bed in the cancer annexe.

The will of the late Mary H. Russell contains bequests of $5,000 to the Germantown Hospital and $6,000 to the Child's Homeopathic Hospital.

Under the will of the late Mrs. Jane McKee Norris the Presbyterian Hospital, of Philadelphia, will receive the sum of $35,000 for various purposes.

A contingent bequest of $1,000 to the German Hospital, of Philadelphia, is contained in the will of the late Otto Backmeier.

All except $73,000 of the $400,000 estate of Katherine Allen, of Worcester, Mass., is disposed of in public bequest. The Worcester Polytechnic Institute and Memorial Hospital are named as residuary legatees and will receive about $100,000 each.

Hermann Knapp Memorial Eye Hospital Formally Opened.—The new building of this hospital, at Fifty-seventh Street and Tenth Avenue, New York, was formally opened on Saturday, December 13th. The institution was founded in 1909 by the late Dr. Hermann Knapp under the name of the New York Ophthalmic and Aural Institute, at 44 and 46 East Twelfth Street. The inadequate facilities of the old hospital building, the passing of the locality into business with the construction of new buildings, and the advance in hospital construction suggested the necessity of finding a new home for the institute in a part of New York further uptown, where a modern hospital could be erected. For this purpose Dr. Hermann Knapp succeeded in enlisting the generous interest of the trustees and other friends of the institute, and a building fund was collected through his personal appeal. The building is a seven story structure, completely equipped with the latest appliances for the treatment and teaching of diseases of the eye. The roof is adapted for a roof garden, which is an innovation for eye hospitals, but is a desirable addition to all hospitals in a large city. The building consists of six floors: The-rooms: Dr. Arnold Knapp, executive; Dr. H. H. Tyson, Dr. J. M. Mills, Dr. J. B. Lynch, Dr. O. Schirmer, Dr. E. Torok, and twelve assistant surgeons and clinical assistants.
Pith of Progressive Literature.

MÜNCHENER MEDIZINISCHE WOCHENSCHRIFT.

Organ Specificity of the Proteolytic Splitting Ferments.—A. Fuchs treated rabbits with intraperitoneal injections of organ extract and tested, after the lapse of a certain period, for the presence of specific splitting ferments (Abwehrfermente) in their blood. All tests proved an absolute organ specificity of the ferments. In one animal, after the injection of kidney substance, only kidney substance was split up, and after the injection of muscle only muscle was split up and no other tissue. There is no species specificity. The ferments attack the corresponding organ of the most diverse animal species in equal degree.

Intravenous Melubrin Therapy.—B. Hahn recommends the intravenous injection of a fifty per cent. solution of melubrin in patients with sensitive gastrointestinal tracts and in cases which are influenced with difficulty when the medicine is given by mouth. When 2.5 to three gm. of this solution is given intravenously three times daily, an intensive and direct influence can be exerted on the causative factors of the disease. The yellow color which the preparation assumes after its solution and sterilization is of no consequence. No disintegration occurs, nor is the therapeutic value of the preparation in any way diminished.

Action of Uzara and Opium.—O. Hirz says the basic principle of uzaron action is an inhibition of motor acts in the organs having unstriped muscle tissue (intestine, stomach, bladder, and uterus). It is brought about by a stimulation of the inhibitory sympathetic fibres. The action of uzaron is, on the whole, more lasting than that of the easily decomposed adrenalin and the easily soluble salts of the opium alkaloids. The point of attack for the opium lies in its action on the autonomic nerve endings and in the musculature itself. The action is a paralytic one. The pharmacodynamic advantage of one physiological function (a sympathetic inhibitory action) of uzaron is thus seen. To this must be added the tonic action of the uzaron on the heart and vessels, particularly in the splenic area, in contradistinction to the disturbing narcotic properties of opium and its derivatives.

Therapy of Pernicious Anemia.—Windersheim obtained a most gratifying result in a case of pernicious anemia by repeated intragluteal injections of ten c.c. of fresh warm human blood taken from the basilic vein. The technic is simpler than the one recently recommended by Weber.

Regeneration of Axis Cylinders in Vitro.—R. Ingebrigsten gives, for the first time, proof that nerves grow out from small pieces of cerebellum of young cats and guineapigs if the latter are grown in plasma. The same phenomenon may be observed in cortex and spinal ganglion. The newly formed filaments do not anastomose, but grow isolated into the plasma without being accompanied by glia tissue. The conclusion may be drawn that in regenerative processes also in the body, axis cylinders grow out of themselves without the aid of the surrounding tissue.

Active Portion of Beck's Bismuth Paste.—F. Rost says that the active, namely, the stimulative connective tissue substance, in Beck's paste is not the bismuth but the vaseline. Therefore the not altogether nonpoisonous bismuth may be omitted without compromising the efficacy of the paste.

Influencing Abnormal Leucocyte Counts by a New Method.—O. Veraguth and R. Seyderhelm were able to change the pathological blood picture in leukemia, morbus maculosus Werlhoffii in a favorable manner by certain definite changeable applications of a weak current. Since this electric influence seems to possess a selective destructive action on pathogenic blood cells, it may be assumed that a similar influence is exerted on other cells, whose presence in the organism is equivalent to disease, by a weak electrical current.

Examination of the Sugar of the Blood in Chronic Nephritis.—L. Borchardt and W. Benigno state that in the chronic nephritides not complicated by fever or uremia, a slight grade of hyperglycemia is present in all cases where sodium chloride, that is nitrogen, is retained by diseased kidneys. Vice versa, excretion of the sugar of the blood is normal in normal sodium chloride and nitrogen excretion. Sodium chloride retention and hyperglycemia have one common cause; both are conditioned by increasing resorption of sodium chloride, more specifically by grape sugar in the urinary tubules.

Abderhalden's Seroreaction in Epileptics.—O. Binswanger finds that in fully developed epileptics with paroxysms, the serum regularly contains protective ferments (Abwehrfermente) against cortical substance; thus there is a possibility of differentiating epileptic from hysterical fits by serodiagnosis. If the protective ferments are absent in the periods intervening between the attacks, then it may be assumed that a progressive anatomical change has not yet taken place, and that no progressing mental deterioration is, for the time being, to be feared. A negative Abderhalden reaction between the periods may also be due to the circumstance that splitting up of the brain substance is overshadowed by splitting up processes in other parts of the body. Epileptic equivalents, dream states, have not thus far shown splitting up ferments.

Meningitis saturnina.—E. Plate reports the case of a man who had previously suffered from lead colic, but who had for years not handled lead products. The patient began to complain of increasing headaches, stiffness in the muscles of the neck, slight clouding of consciousness; later he had vomiting and fever. Lumbar puncture shows pressure of 440 mm. Hg. The fluid is rich in lymphocytes. The blood contains numerous basophile nucleated erythrocytes. After a severe attack of colic and nose bleed an improvement occurred with general regression of all the symptoms. The lumbar pressure remained increased for some time, and the spinal fluid did not lose its lymphocytes.

Treatment of Fracture of the Forearm with Pegs.—G. Schöne says that for individual cases of old forearm fractures which require a tight and
reliable peg, the author recommends the following procedure: Narcosis, exposing the points of fracture, refreshing the fractured parts, and removing the callous mass infringing upon the marrow cavity; a longitudinal incision four cm. long over the extensor surfaces of the radius immediately above the wrist joint; exposure of the bone, a trephine opening over the marrow cavity; introduction of a flexible silver rod by means of a forceps against the point of fracture and beyond this in the marrow cavity of the proximal fragments; by hammering, the rod is pushed out as far as possible and then the point of fracture is controlled by proper position of the fragments; closure of the wound; repetition of similar technic on the ulna, with one difference, namely, that the boring is made at the proximal end.

Treatment of Abdominal Wall and Muscular Pelvic Floor in Puerperal Women by the Bergonie Technic.—Brommer reports that with the Bergonie high frequency current it is possible to strengthen the relaxed abdominal wall of the parturient woman. Much significance is placed on the strengthening of the levators, whose stretching plays such an important role in the production of prolapse. The apparatus was successfully applied after laparotomies, also in obesity. Further, the muscle atrophies due to inactivity following fractures are satisfactorily stimulated by these rhythmic contractions.

Disturbances in Heart Conductivity in the Course of Salvarsan Treatment in Late Secondary Lues.—H. Fuchs reports the case of a man with secondary syphilis, but clinically normal heart, who had received within four weeks 2.3 grams salvarsan intramuscularly and intravenously, in whom developed after the last injection of 0.6 gram salvarsan the signs of a typical heart block, bradycardia, dissociation of the heart action, differences in frequency between the radial and jugular pulse. These symptoms subsided in a week under the influence of continued, mild antiluetic treatment. The author supposes that after the last injection the localized nests of spirochetes in the bundle of His were attacked and destroyed. This destruction freed the endotoxins and injured the weakened muscle fibres.

Body Accompaniments of Psychic Changes, with Special Consideration of Psychogalvanic Reflex Phenomenon.—J. Leva proves with the plethysmograph that psychic changes produce body changes. It is sufficient for a thought of motion to produce in the organ volumetric changes. These variations depend, in all probability, on changes in blood distribution (blood displacement). A further body manifestation of psychical changes is the increase in the strength of the electric current passing through the body while a thought is being generated (so called psychogalvanic reflex). This phenomenon is strongest when the electrodes are placed on portions of skin rich in sweat glands. Since atropine causes the psychogalvanic reflexes to disappear, it may easily be supposed that the phenomenon bears a causal relation to the activity of the sweat glands. The important fact is thus established that our sweat glands are also functioning, even when no results of their activity are evident.

Simple and Inexpensive Fermentative Saccharometer.—W. Reusch describes an apparatus, a modification of the Lohnstein's fermentation saccharometer, distinguished by stability, simplicity of construction, and inexpensiveness.

Ambulatory Tuberculin Treatment.—J. Hartmann answers the objections of E. Hartmann, and asserts that he has seen a number of permanent cures result from the ambulatory treatment with tuberculin. The physicodyetic institutional treatment is the best in this disease when carried out for a long period of time; many patients, however, cannot interrupt their work for this length of time, and for such cases the ambulatory treatment with tuberculin is very desirable.

FOLIA UROLOGICA.

August, 1913.

Bilharziosis.—G. Ekhorn reports a case which gave as a chief symptom terminal hematuria. The patient had been sick for six years, and died of an infectious pyleonephritis. The cystoscopic examination showed a characteristic picture. The top of the bladder was covered with pale gray villosities which resembled fur.

Supernumerary Kidneys.—F. Suter has collected from the literature seventeen cases of supernumerary kidneys, and adds two of his own; one of these was diagnosed before operation. The diagnosis is made by the occurrence of an extrareteral orifice and ureter. The ureter of the upper kidney opens into the bladder near the median line, and, therefore, nearer the urethra than the ureter of the lower kidney. These kidneys occur with equal frequency in men and women, and the supernumerary kidney is found as often above as below. They generally become hydronephrotic. In but three of the nineteen cases was the diagnosis made before operation.

September, 1913.

Cystophotography.—B. Klose has had Lowenstein, of Berlin, manufacture a cystoscope with which instantaneous photographs of the bladder may be made. The size of the cystoscope is 23 F. The pictures which he has taken of normal and pathological conditions are marvelous. As far as we know, no other such photographs of the bladder have ever been taken.

Spontaneous Fracture of Vesical Calculus.—H. Bastos describes a case in which a patient passed spontaneously many portions of an evidently fractured calculus. The case was operated in and many more fragments were removed. It is believed that the fracture is caused by some physicochemical changes within the stone and not by bladder contractions, or by bacteria. Spontaneous fractures are extremely rare and occur about once in ten thousand cases.

PARIS MÉDICAL

November 20, 1913.

Value of Moriz Weisz Reaction in Pulmonary Tuberculosis.—Tecon and Aimard studied the reaction for urochromogen in the urine in 225 cases of lung tuberculosis. The test is performed by adding three drops of a one in 1,000 solution of potas-
sium permanganate to urine diluted with two volumes of distilled water, the production of a golden yellow color indicating a positive reaction. Of forty-one cases with lung cavities in the authors’ series only nineteen yielded a positive result, while other authors have reported 100 per cent, of positive results in such cases. This difference may have been due, 1, to the well known influence of altitude on secondary infections, the authors’ tests having been made at Leysin, Switzerland; 2, to the fact that sanatorium, and not ordinary hospital patients, were under examination. The Ehrlich diazo reaction was conducted as a parallel test in the entire series. The authors conclude that the Weisz test is superior to the Ehrlich, being simpler and more sensitive. It is, however, uneven in its results, which is not surprising, since the underlying factors are as yet largely unknown. It is never positive in the first stage of tuberculosis, and the information it yields is no greater than that afforded by clinical examination. Often its occurrence is not related to the gravity of the cases tested. Only frequently repeated positive results appear to be of value. The fact that a positive reaction is reported to have occurred in the urine of normal persons deprives the test of much of its value.

**SYPHILITIC REINFECTION AND CHANCROIDFORM LESIONS.**

—G. Milian states that the term reinfection should be applied only where syphilis recurs with the identical features present in the original infection, viz., history of exposure, incubation period of fifteen to thirty days, typical chancre with glandular enlargement, and secondaries developing at least forty-five days after the appearance of the chancre. There exist chancroidic secondary and tertiary lesions, which must not be confounded with the chancre of true reinfection. Distinction is made by the absence of related glandular swelling in the former instances and by the usual presence of other signs of the corresponding period, e.g., headache, insomnia, multiple glandular enlargements, buccal lesions, etc. The recent increase in the frequency of reinfections is due both to closer study of the disease and the fact that more powerful means of treatment are available.

**PRESSE MÉDICALE.**

November 25, 1913.

**Coxa vara.**—A. Broca asserts that relief of weight bearing upon the involved femur is the only rational procedure in coxa vara. The patient should be kept in bed, with the limb in continuous extension in the abducted position. This will not only promptly and completely relieve the pain, but may slightly open out the abnormally reduced angle between the femoral neck and shaft. When after a few months of rest, the upright posture is resumed, the abductor muscles should be strengthened by massage, gymnastic exercises, and if necessary, faradic stimulation. As the morbid condition almost always comes to a standstill at the termination of the period of growth, it is best to defer operative treatment, if such should be required, until this time, when the abnormal malleability of the bone has disappeared. The best surgical procedure is a subtrochanteric osteotomy, transverse or oblique, according as there is slight or pronounced shortening.

**COAGULATION OF CEREBROSPINAL FLUID IN TUBERCULOUS MENINGITIS.**—R. Debré and J. Paraf report a case of meningitis, ending fatally in thirty days, in which the fluid removed by lumbar puncture on seven successive occasions underwent prompt coagulation in vitro. A large number of both red and white blood cells were found in it, and its color was yellow, with greenish fluorescence. Interest was lent the case by the fact that the tubercle bacillus was detected in the fluid and inoculation of a guineapig gave a positive result. The symptoms for the most part were those of tuberculous meningitis, though the violence of the headache, marked rigidity and fever at first suggested a nontuberculous meningeval infection.

**SUPERHEATED AIR IN THE TREATMENT OF SUPPURATING WOUNDS.**—H. Rozès points out that hot air is in the first place bactericidal, destroying both aerobes and anaerobes, and after this effect has been exerted, promotes healing, with the production of pink colored, smooth, pliable and painless scars comparable only with those furnished by radium. After referring to the good results already reported from the projection of a stream of heated air upon varicose, tuberculous, and syphilitic ulcerations, myoses, gangrene, burns, chancroids, and superficial cancerous lesions, he mentions two cases with superficial contused wounds, two of wounds with an open fracture, and ten of operative wounds in which the usual dressings and cauterization had failed to cause healing, where the hot air treatment gave excellent results. The applications were given usually on alternate days—daily in a few particularly rebellious cases—for ten to fifteen minutes, and were followed by covering of the wounds with a dry dressing, iodine tincture being painted around in a peripheral zone. The temperature of the air used was always 100° to 200° C. at the outlet from the apparatus and 50° to 70° at the skin level. No untoward local or general effects were noted except in one case, where a second degree burn resulted, later healing rapidly. In eight cases complete healing with excellent cicatrices was observed, while in the others there was marked improvement, indicating that entire healing would have followed in a few days if the patients had not hurried off from the hospital. The membrane of cicatization developed with great rapidity under the hot air. A contused wound of the leg measuring five by ten cm. healed completely after three treatments.

**BRITISH MEDICAL JOURNAL.**

December 6, 1913.

**The Large Intestine and Its Work.**—Joseph Griffiths traces the development and function of the large intestine from the lower animals to man, and comes to the conclusion that we derive something from the process of absorption which goes on there which is essential to the feeling of complete well being. What this substances is, is not yet known; it is present in very small quantities apparently, and is probably absorbed from the intestine lying between the cecum and the sigmoid. The large in-
testine is so constructed anatomically as to provide
a mechanism for the delay of the expulsion of the
intestinal contents, to secure their perfect mixing,
and to provide for the absorption of fluid. It is
possible, also, that there is considerable nutritive
matter absorbed from the large intestine; matter,
digestion of which is accomplished, at least in
part, by the action of the bacteria which flourish in
this portion of the intestine. The large intestine
also provides an adequate mechanism for the transit
and expulsion of fecal matter. As this loses its
water through absorption, it is passed along the
canal into a region which contains mucus glands
to provide the necessary lubricant for the ever hard-
ening masses. With the onward progression of the
fecal mass there is an increasing production of mu-
cus, so that normally there is no lack of lubricant.
A delay in the transit of the intestinal contents
along the large intestine is associated with well rec-
ognized symptoms, depending in their severity upon
the degree of decomposition which the food under-
goes, and the extent of the absorption of noxious
products. In addition there is a resultant increase
in the amount of fluid resorbed into the body tis-
sues. This excess of fluid is, therefore, an indica-
tion of stasis in the large intestine, and accompanied
or precedes the symptoms of autointoxication. The
tongue is so constructed as to contain a great rela-
tive amount of loose areolar tissue. The excess of
fluid in the tissues of the body is most readily ob-
served in the tongue, which, in this condition, be-
comes enlarged and shows the indentations of the
teeth. The author does not agree with Metchni-
koff, or Lane, and their followers, that there is no
good in the large intestine, but, on the contrary,
holds that its functions are of great value in the
maintenance of a feeling of being “in the best of
health and spirits.”

Traumatic Intramuscular Ossification.—John
Morely finds that the ossification in the muscle is
always due to the migration into it of free oste-
oblasts, which have been dislodged by traumaism
and rupture of the periostea. The presence of a
blood clot in the region between the injured peri-
ostea and the contused muscle greatly increases the
probability of a subsequent ossification occurring in
the muscle. Morley’s conclusions are: 1. Trauma-
tic intramuscular ossification, or myositis ossificans,
is due to migration of osteoblasts into adjacent con-
tused muscle and blood clot, after destruction of the
periostea and loss of its function as a limiting
membrane to the growth of bone. It is essentially
the same process as callus formation. 2. The con-
dition may be produced experimentally in animals
by reproducing to some mechanical conditions by
an aseptic open operation. 3. In a case of difficulty
in diagnosis from sarcoma open exploration is ad-
visable. 4. Simple excision is usually, though not
invariably, followed by recurrence. 5. Conservative
treatment condemns the patient to long periods of
disability, which may occasionally be permanent.
6. Excision combined with grafting of deep fascia on
to the denuded surface of bone gives the best pro-
spect of rapid and complete recovery, and is urged
for all cases not complicated by ossifying periar-
thritis. 7. Osteoblasts and chondroblasts are the
same cells under different conditions of nutrition.

The Daily Weight Chart as a Guide to Tubercu-
lcin.—H. Warren Crowe weighs his patients
daily, at the same hour, in the same clothes, and
under conditions as nearly constant as possible.
The curves of weight show several forms, which
are found to follow closely the curves of the op-
sonic indices in the same patients, the parallelism,
however, being absent where slight changes in the
opsionic index are concerned. These weight curves
also follow closely the changes in the subjective
symptoms of well being or the reverse. If the
weight curve shows a fall after a dose of tuberculin,
it is an indication of a marked negative phase, and
that the dose used was too large. A constantly in-
creasing weight calls for an increase in the dose of
tuberculin, and is indicative of a favorable response.
The variations in weight from day to day are not
matters of a few ounces only, but are often as great
as two pounds. The method is easy, delicate and
accurate.

Bacteriology of the Mouth in Maori Children.
—H. P. Pickering and S. T. Champaloup studied
the organisms present in the mouths of a number of
Maori children who were apparently decidedly re-
sistant to dental caries. They found that the organ-
isms were quite as abundant both in variety and in
numbers as is the case in the mouths of Europeans
who are subject to dental caries. The numbers and
types of organisms are, therefore, not at the bottom
of the immunity of the Maoris to dental caries.

LANCET.
December 6, 1913.

Change in the Pelvis in a Case of Prepuberal
Atrophy of the Testicles.—H. Batty Shaw and
R. H. Cooper found several interesting bony
changes in their patient, a man twenty-four years
of age, six feet three inches tall, and weighing only
106.5 pounds. The changes associated with pu-
berty never developed, and his testicles remained
small until the age of seventeen years, at which
time they began to atrophy. In addition to a very
boyish, high-pitched voice and absence of pubic,
axillary, and facial hair, interesting phenomena
were found in the osseous system. His trunk mea-
sured twenty-two inches from the suprasternal notch
to the symphysis pubis, a measurement exactly sim-
ilar to that of a normal man; from the symphysis to
the ground he measured forty-two inches, whereas
the normal man measures only thirty-three and a
fraction. His pelvis was of peculiar shape and di-
ensions; its external measurements here given are
followed by the corresponding ones for a normal
man, given in parentheses. Interspinous, nine
inches (nine); intercrystal ten and three quarter
inches (eleven and one half); external conjugate,
seven inches (seven and a half); between posterior
superior spines, four inches (four); between the
tuberosities of the ischia, three and a quarter inches
(four). Röntgenograms of his pelvis showed the in-
let to be markedly cordiform, the transverse diame-
ter being to the anteroposterior as 57 is to 67. The
there was marked inward protrusion on each side at
a point corresponding to the acetabulum. There was
an exaggerated curvature of the dorsal spine, ex-
tending into the upper lumbar region, leading to a
stoop, and not compensated for by any lumbar lor-
dosis. Ossification in general was defective, there
being no bony fusion at the epiphyseal junctions in
some of the long bones, deficient union in others,
and a marked general lack of density of bony tissue.
The pituitary and thyroid glands were apparently not
enlarged. The question of the relation of the bony
changes to the absence of the testicles is problemat-
ical. The general features correspond closely to
those found in prepuberal eunuchs, except for the
peculiar form of the pelvis. This is possibly to be
accounted for on the basis of a late and defective
union of the several pelvic bones where they go to
make up the acetabular cavity, and an inward pro-
trusion of these due to weight.

Causes of Disappointment Following Removal
of Tonsils and Adenoids.—William Wilson says
that, in children suffering from adenoids, a mass of
adenoid tissue will be found occupying the region
just behind the Eustachian orifices and pressing
more or less on the posterior portion of the Eusta-
chian cartilage. This growth is not recognized and
is not removed, so that deafness often remains,
owing to the inability of the muscles to open the
orifice of the Eustachian tubes against the resis-
tance of this adenoid mass. This mass should be
sought in every case and, if present, removed by
using the smallest ring knife or Mackie’s curette.
Many failures also are due to neglect to examine
the nose to determine the condition of the turbi-
nates. Hypertrrophy of the posterior portion of the
inferior turbinates is very common in adenoids, and,
if not removed, causes great obstruction to respira-
tion, and increases the tendency to deafness. Sep-
tic infection or hypertrophy of the lingual tonsil
is frequently overlooked and is the cause of persist-
ent throat cough. Deviation of the cartilaginous
septum of the nose is often present, and should
be corrected in order to secure a satisfactory final re-
sult. The aftertreatment of these throat cases is no
less important than the primary operation and
should include breathing exercises every day, week-
ly politerization for six weeks or more, and dental
apparatus designed to correct the narrow palatal
arch.

Perforation of Gastric Ulcer into the Heart.—
Frank E. Tylecote’s patient was a woman seventy
years of age, who went to bed feeling as well as
usual and was found dead the next morning. There
was no history obtainable, save that some ten
months previously she had complained of indefi-
nite pains about the lower part of the chest and epi-
gastrum. A physical examination at this time did
not reveal any signs of organic disease. A post
mortem examination showed the cause of death to
have been the rupture of an old gastric ulcer into
the left ventricle of the heart. The diaphragm,
stomach, pericardium, and heart were all firmly and
mutually adherent over a considerable area around
the ulcer. There had evidently been a fairly gen-
cral productive serositis in both pleural sacs and
the abdomen. The ulcer was very deep, soft, and
was situated on the anterior gastric wall near the
lesser curvature. A search of the literature brings
forth only four other instances of perforation of a
gastric ulcer into the heart. In three of these also
the ulcer was located on the lesser curvature, the
fourth being on the anterior wall.

JOURNAL OF LARYNGOLOGY, RHINOLOGY, AND OTOLGy.
October, 1913.

Accessory Sinuses.—E. J. Moore is of the
opinion that after a thorough curettage of one of
the accessory sinuses, with special reference to the
frontal and maxillary, the cavity in time is entirely
obliterated by the formation of fibrous tissue, thus
making unnecessary the disfiguring operations that
are now frequently advocated. The curettage is
usually preceded by the swabbing of the cavity with
a tampon, small enough to enter every recess, and
impregnated with a ten per cent. solution of zinc
chloride. Following the complete removal of the
lining membrane with the curette, the cavity is
packed with a strip of iodiform or vioform gauze,
with one end coming out of the nose and the other
end at the internal angle of the cutaneous incision
between two suture points. The gauze is removed
in from three to five days, and at the end of five or
six weeks the sinus should cease to exist.

BOSTON MEDICAL AND SURGICAL JOURNAL.
December 11, 1913.

Condition of the Upper Region of the Ab-
domen in Relation to Disease of the Gallbladder.
—Charles G. Stockton calls attention to the follow-
ing as important among the causes of obscurity in
diagnosis in disease of the gallbladder: The devel-
opment and persistence of symptoms in an organ as
results of disease in another, usually, but not neces-
sarily contiguous part; comparatively trivial lo-
cal disease accompanied by severe and misleading
symptoms; the simultaneous presence of two dis-
eases; the influence of diathesis and metabolic pe-
culiarities, not only in the inauguration of symp-
toms, but also in masking conditions and in delay-
ing recovery. These four cases he deals with at
some length, and says under the last heading:
“‘This generation will scarcely listen to one who ad-
vises a course of colchicum, alkalis, a diet scientif-
ically prescribed, systematic diaphoretic baths,
massage, and out of door exercise in the cure of in-
fec tion of the urinary or biliary tract, but surely
the time is at hand when the obscure subjects of gout,
oxaluria, and other metabolic defects will stand
again in the foreground, not only in explaining pathogenesis, but in guiding our therapeutics.”

Acute and Chronic Suppuration of the Middle
Ear.—G. L. Tobey simply tries to drive home
the facts that all and every suppuration of the mid-
dle ear is a serious menace to life, and that the ma-

this JOURNAL for July 5th, p. 41.

Scientific Basis for Vaccine Therapy.—R. M.
Pearce summarizes as follows: 1. Prophylactic
vaccination rests on a sound scientific basis of experimental study and clinical observation. 2. Curative vaccination has no sound experimental basis, but the application of the general principles of immunity as well as clinical observation offers a plausible basis for the treatment of localized, more or less chronic infections and of "carriers". On the other hand, there is at present no satisfactory basis for curative vaccination in the acute, self-limited diseases characterized by general dissemination and systemic infection. 3. The only logical method is the use of autogenous vaccine. 4. Therapeutic vaccination, if it is to be placed on a scientific basis, should be regarded as a method of treatment based on the study of the individual and his infection, and not as a ready made method capable of the universal application of stock vaccines. The use of vaccines in diseases of doubtful or unknown etiology is unscientific and ethically indefensible.

5. Every physician practising vaccination should bring to bear every method of laboratory and clinical investigation which promises light, and preferably should work with a trained immunologist.

6. In the interpretation of results, it should be borne in mind that vaccines rarely, if ever, cure, but act rather in aiding a process which tends to recovery by stimulating a languid process of immunization.

**Theory of the Cause of Ectopic Gestation.**—O. V. Huffman states that in May, 1913, he announced a theory he had formulated which explains the cause of ectopic gestation wherever located—the anomalous implantation area theory. He now reports that he has examined sixty-eight specimens of tubal gestation, and, notwithstanding the difficulties attending such examinations, has found malformation in fifty-four per cent. of them. This evidence, beside the negative findings in regard to any obstruction or inflammation, is sufficient to warrant the establishment of the theory in question, which he regards as the most logical of all the explanations for ectopic gestation because it rests primarily on the mutual relation of fecundated ovum and implanting site.

**Striking Acquiem of Visualizing Power and the Development of Dreams Following a Cerebral Tumor Extraction.**—E. G. Grey and L. E. Emerson state that the rapid reappearance of visual imagery noted has clear cut analogies in other aspects of cerebral pathological physiology, but just why there should have been a selection for visual imagery alone is not so clear. Auditory and motor imagery apparently showed no changes in intensity before and after the surgical treatment.

**Hyperthyroidism of Intestinal Origin.**—J. C. Hemmeter reports three cases in which a chronic colitis of many years' standing preceded the symptoms of hyperthyroidism, and states that treatment directed to the intestine has proved more efficacious than treatment by thyroidine, antithyroidine, or Beebe's serum.

**Efficiency in Nursing.**—W. Gilman Thompson makes an urgent plea for the study of greater efficiency in nursing, in order to conserve the nursing force met with in any hospital, and for the greater use of common sense appliances for promoting the comfort of patients in bed. If, he says, the nursing system of to-day is being overweighted with theory and pedagogy, to the detriment of more legitimate practical and humanitarian aims, physicians have no one to blame for it but themselves, through their lack of cooperation and increasing tendency to permit training schools to be managed by extraneous influences, who manipulate the curriculums, and arrogate the responsibilities which are primarily the function of the doctor.

**New Method of Anastomosing the Ovarian Tube or Vas deferens.**—S. L. Christian and E. L. Sanderson, in order to prevent obliteration at the line of sutures, pick up the cut ends, a piece of No. 0 twenty day cagut is inserted three eighths inch into each end of the tube, and the ends are brought together with two apposing cagut sutures.

**MEDICAL RECORD**

December 27, 1913.

**Surgical Treatment of Diffuse Suppurative Labyrinthitis.**—P. D. Kerrison, having referred to the gravity of the lesion, remarks that the question of operating in any case depends so largely upon the surgeon's interpretation of symptoms that it is difficult to formulate any rules which might not lead to serious error. There are, however, certain grave conditions which in themselves constitute a more or less definite call for surgical intervention, and among these are: 1. Labyrinthine infection quickly following upon surgical injury of the stapes; 2. suppurrative labyrinthis complicating acute purulent otitis media and accompanied by high fever; 3. evidences of a latent suppurrative labyrinthitis, plus symptoms of chronic middle ear suppuration, calling for relief after the acute stage of a suppurrative lesion of the labyrinth has passed; 4. physical evidences, found during the radical operation, of intravestibular suppuration. In speaking of the surgical treatment he states that the point he wishes particularly to emphasize is that the acute stage having passed without evidences of meningeal involvement, we may assume that the natural pathways of intracranial infection are to some extent safeguarded by inflammatory thickening of the membranous structures; the problem is whether to operate promptly, in order to forestall meningeal infection, or delay operation in the hope that the acute stage may pass without intracranial involvement. Operative intervention having been determined upon, two facts should be borne in mind. First, that aside from the defect or lesion at the oval window, the bony capsule is usually not diseased; second, we must enter a peculiarly unprotected field, in which any unnecessary manipulations may actually conduce to meningeal infection. Reasonable operative speed and the reduction of the operation to the simplest possible technic are therefore important factors. The technic is described.

**Radium and Röntgen Therapy in Cancer.**—Isaac Levin summarizes as follows: 'The radium and Röntgen rays are no more of a cancer cure than salvarsan is a syphilis cure, but these rays are therapeutic agents deserving at least as much consideration as surgery. Overenthusiasm is as injurious to scientific work as over pessimism is.
Sober joint work in this field of the physicist, the biologist, and the clinician will surely be fruitful of far reaching results in the therapy of malignant tumors.

Radium in the Treatment of Cancer.—W. H. Diefenbach, after eleven years of experience with the employment of radium in efforts to control neoplasms, expresses the conviction that the battle against malignant growths is not as confined and hopeless as is generally pictured. In many inoperable or advanced lesions the combination of surgery with radium radiation will prove successful.

Chorioepithelioma; A Fatal Case.—W. W. M. Hartshorn concludes, first, that chorioepithelioma, defined as a neoplasm apparently due to an unrestrained proliferation of chorionic epithelium, is as a rule a highly malignant blastoma which usually follows pregnancy. 2. Inasmuch as it most commonly arises after hydatid degeneration of the placenta, patients affected with it should be carefully watched for a long period after the expulsion of the uterine contents. 3. Persistent bleeding following abortion or pregnancy should be regarded with suspicion. In such the curettings should be subjected to pathological examinations. 4. Although chorioepithelioma is as a rule highly malignant, the prognosis is not hopeless; in a few cases the patients recover even after general metastatic involvement.

Acute Phlegmonous Cholecystitis; Case with Gangrenous Enteritis.—A. E. Roussel concludes that gangrenous cholecystitis may occur independently of impacted gallstones or typhoid fever, and may be secondary to a similar process in the intestinal tract; also that it must be admitted that gangrenous enteritis independent of obstruction, intussusception, or malignant disease may occur as the result of some virulent infection, probably streptococcic, and may extend into the gallbladder by continuity of structure. Furthermore, such infection may gain access to the gastrointestinal tract directly or indirectly from localized foci. That the general organs of the chest and abdomen must be below par for the culmination of this process, must be acknowledged, since all the cases enumerated by him showed more pronounced changes in the gallbladder and intestines, the more disturbed were the other viscera. In the face of these facts, the condition must be regarded as a fatal disease.

AMERICAN JOURNAL OF TROPICAL DISEASES AND PREVENTIVE MEDICINE.

October, 1913.

Filiform Nematode Passed from Urethra.—Allen J. Smith and O. E. Denney describe a worm passed after the taking of a large dose of spirits of turpentine. The specimen is of a light brownish red color, almost twenty inches in length, and averages about 0.5 mm. in thickness. There had been pain in the back and bladder region, before the passage of the nematode, but no disturbance of nutrition. In view of the incomplete alimentary canal, the practical absence of generative parts, and other anatomical peculiarities of the worm, the authors consider it an undeveloped form, probably the second larval stage, of a Mermis. Leidy, in 1880, described a somewhat similar specimen, which was later reexamined by Stiles and named by him Aganomermis rectiformis. How infestation of human beings by these nematodes, practically always parasites of insects, is effected, cannot at present be explained.

Rapid Cure of Polyneuritis gallinarum by Intramuscular Injection of a Substance Isolated from Rice.—C. Wellman, A. C. Eustis, and L. C. Scott repeated Funk’s experiments on the cure of the polyneuritis of fowls (analogous to beriberi) with an extract of rice polishings and also made a careful pathological study of animals dead of the disease. Two of the first seven chickens receiving the extract recovered completely, and further work of this kind is in progress. The curative substance proved readily absorbable from intramuscular injections, and this is taken to show that it acts independently of the liver and alimentary canal. The nerve degeneration in the polyneuritis was found confined principally to disturbance in the myelin sheath of the fibres. Neither the sensory nor motor tracts of the cord, medulla, or brain showed any change. Subdural hematomas, due probably to increased vascular permeability, were found, and may, through spinal irritation, be the cause of the convulsions usually coincident with the paralytic symptoms.

ANNALS OF SURGERY.

October, 1913.

The Treatment of Tuberculous Cervical Adenitis.—George P. Muller believes that after a careful history has been obtained and an examination made, the portal of entry can usually be surmised and, if necessary, the tonsil, adenoid, or carious tooth should be removed, or any ulcer, scab, pediculosis, otitis, etc., attended to. In those cases seen early with only a small area involved and where the child is in good general health, an operation should be advised. If the social position permits, this dissection should be confined to the microscopic group with a minimum scar and the child sent to the seashore and kept from school for one year; the general and hygienic details of treatment being carried out with scrupulous care. In the case of the poor child or where such cannot be carried out, he believes the entire submaxillary and cervical chains above the omohyoid should be excised. The general treatment must then be carried out at home. If the case is seen late with one or both sides choked up, the x ray is often of advantage in reducing the hyperplasia and a radical dissection may be carried out at an opportune time. If caseous abscesses, sinuses, etc., exist, they should be opened up, curedt, and an effort made to thoroughly clean up the tuberculous granulation tissue; after this the x ray is often invaluable in promoting healing. He prefers the transverse incision whenever possible, especially for the submaxillary and upper part of the deep cervical. When the mass has crossed posteriorly beneath the muscle or involved the posterior superficial cervical chain, an oblique incision from the posterior edge of the mastoid along the posterior edge of the muscle to just below its middle and then prolonged trans-
versely to the thyroid muscles will give a large field area. Finally, intratracheal insufflation anesthesia offers immense advantages in difficult cases, although pharyngeal insufflation anesthesia suffices for the easy ones.

Uncomplicated Fractures of the Tarsal Scaphoid.—A. E. Horwitz presents a series of cases, in all of which the symptoms were constant, representing an entity. The injury was slight, the disability, with one exception, not immediate. Crepitus was absent; ecchymosis was slight; the scaphoid was thickened, flattened, and tender; tenderness was elicited along the posterior tibial muscle; the motions at the astragalotibial joint were not impaired; abduction of foot was practically the only motion limited; and the long arch of the foot was depressed. The radiograph in all cases revealed a fracture of the tubercolo. No other bone was involved. In all cases a traumatic flat foot resulted. In the four adolescent cases muscle tension was the only injury. In the adult cases two were of this same class, the other two received injuries of a more severe type. The injuries reported by others were of a severe crushing type which resulted in fracture of several bones or in comminution of the scaphoids. The treatment in those cases which were seen immediately, consisted in immobilization for ten or fourteen days, followed by massage and the use of felt padding under the arch. A cork pad was later built in the shoe; in the cases not seen early strapping and felt pads were used till pain was relieved; then a cork pad was placed in the shoe. A metal plate such as is commonly used is harmful in this class of lowered painful arch, as it produces pressure on the painful prominent scaphoid, and keeps up the irritation. The soft felt pad is to be used until all pain is relieved.

Suction Tip for Aspiration in Abdominal Operations.—Eugene H. Pool says that the important feature of the apparatus in abdominal cases is the tip, which consists of an inner suction tube and an outer protecting tube. The inner tube has two openings at its tip. The outer tube has numerous perforations in its distal third and several openings at its proximal or outer end so arranged that the hand of the operator cannot occlude them. These openings at the outer end allow a column of air to pass freely from outside of the wound between the outer and inner tubes to the end of the inner tube. In consequence, a vacuum cannot be formed under any conditions. While fluids which are not too dense and viscous pass through the lumina of the outer tube to the tip of the inner tube where they are aspirated, the intestine or omentum is not sucked into the fenestrations. While suction may be produced by various methods, he uses an ejector attached to the steam pipe in the engine room, whence a metal pipe leads to the operating room. A noncollapsible rubber tube (known to the trade as “pressure” tubing or “four ply insertion” tubing) leads from the suction pipe to a gallon bottle under the operating table. It is essential that noncollapsible tubing be used. From this bottle a comparatively short hose of the foregoing material leads to the operating field. When instruments are prepared for operations the suction tip and the rubber tube leading from the bottle to the field of operation are boiled as a routine practice and are always ready for instant use.

Procedures of Societies.

The Eastern Medical Society.

Stated Meeting, December 12, 1913.

The President, Dr. Joseph Barsky, in the Chair.

Death Due to Intravenous Injection of Neosalvarsan.—Dr. B. Lapowski reported a case of an infant, the first child of a syphilitic mother, born in May, 1913. The first dose of neosalvarsan was injected August 30th, and was not followed by any untoward result. Twelve days later a second intravenous injection was given, at 3 p.m. Until 6 p.m. the child remained well and lively, but then was seized with convulsions. These first convulsions were recovered from, but at 11 o’clock a second series set in, and the patient died comatose at 4 o’clock the next morning; the fatal result being due to arsenical poisonous. No autopsy was made, but arsenic was found in the urine and in the spinal fluid. In commenting on the case, Doctor Lapowski said that the dose of the remedy was carefully graded to the age of the infant, and that in making the injections every possible precaution was observed. In view of such cases, the intravenous injection of salvarsan and neosalvarsan was always a risk. Until they had more definite knowledge concerning these agents, which would enable them to avoid like catastrophies, he thought it would be advisable that their employment should be more restricted, and that they should depend more on the older methods of treating syphilis.

Recent Studies in the Pathogenesis of Cancer.—Dr. Maurice J. Sittenfield gave a résumé of the latest researches, particularly in experimentaion upon rats and mice. He laid stress on the importance of embryonic tissues, and of local predisposition as an etiological factor, and spoke of the increasing belief in the agency of trauma. Incidentally, he referred to some of his own original work.

Radium and Röntgen Therapy in Cancer.—Dr. Isaac Levin said that the action of the radium and Röntgen rays in cancer was well illustrated by that of salvarsan in syphilis. The difficulties of effecting a cure with even a specific remedy in parasitic diseases were enhanced in the case of cancer, for all the clinical manifestations were due to the unlimited proliferation of cancer cells in the region of the primary tumor, or in the local recurrences, and to the transportation and subsequent proliferation of such cells in distant parts of the organism in the case of metastatic tumors. Apparently the rays were minute particles of matter suspended in the air, and it was easy to demonstrate that they could penetrate through the whole body of an organism. Old and highly differentiated cells were more or less resistant to the action of the rays, while young embryonic cells, and cells in a state of active proliferation, were very susceptible. It
was therefore clear à priori that the rays must exert a selective influence on cancer cells. In the present state of their knowledge the radical operative removal remained the paramount method of treatment in cancer, whenever practicable, but in certain cases it might be advisable to radiate before the operation. The fact that some cases which had been regarded as inoperable were made operable through a preliminary radiation, indicated the advantage of such a mode of procedure. Certain cases had also been reported in which, while the radiation did not diminish the size of the growth, the condition seemed to have become more benign, with the result of greatly prolonging life. A preliminary radiation, then, might improve the ultimate results of an operation. The same reasoning indicated clearly the absolute necessity of prophylactic radiation following every operation for a malignant growth. Inoperable cases belonged indisputably to the domain of radiotherapy; but here another extreme should be guarded against. Cases with metastases in the liver or lungs and general dissemination should not be subjected to such treatment as a last resort, for this would serve only to discredit the method and demoralize scientific work. Barely twenty per cent. of the cases referred to him for radium treatment were suitable. Physicians and surgeons should begin to consider radium early in their treatment of cancer cases.

Dr. Howard A. Kelly, of Johns Hopkins University, had had excellent results in the radium treatment of cancer. In superficial cancer he said it was the treatment par excellence. In cancer of the eye, mouth, and ear, if the case were seen early, a cure was effected without any of the deformity from scarring usually left after cutting operations. Here it would do all that surgery could accomplish, and more. There was no mystery about the action of radium as regards metastases, etc. Metastases had to be attacked separately. When this was possible, by this agent, unless they were near the original seat of the disease. In cancer of the larynx some extraordinary results had been achieved. Radium was often of great service in attacking suspected areas. As to the permanency of the cures effected by it in such conditions as malignant disease of the uterus, it was as yet entirely too early to speak with any degree of positiveness, and he did not wish to be understood as claiming permanent cures. It was now five years since he had treated his first case of uterine cancer with radium, and the patient was well to-day; but since then he had met with some recurrences. Other patients had gone two years and more without a recurrence. As to inoperable cancer, he had had a number of cases which had been pronounced of this character in which the patients had been cured (permanently, as far as could be judged at the present time) by means of massive doses of radium. In one such case, of very extensive uterine carcinoma, there had been no recurrence after the lapse of two years. On the whole, it was an unquestionable fact that the use of radium had enormously increased the field of surgery. If it did nothing else in cases of cancer, it stopped the bleeding and discharge, relieved pain, and improved the general condition of the patient. In tumors of the bladder, however, the application of radium occasioned great pain, and the results had not been very satisfactory. The same was true as regards cancer of the rectum, but if the patient was willing to endure the pain, a cure could be effected, in some of the cases at least. In rectal cases it was advisable that a colostomy operation should be done before resorting to the use of radium. All the radium he had in his possession was three grams, and this amount was totally inadequate to the demands now made upon him. He would like very much to have ten grams at his disposal.

Doctor Kelly presented a patient from Missouri, a man in advanced years, who had had an enormous periosteal sarcoma of the forehead, which was now entirely gone; this gratifying result had been accomplished by radium in the short space of forty-eight hours. There had been secondary manifestations on the ear and the jaw, and one of these had disappeared with the main growth. Of the other, there was still something left, and it might be necessary to use radium on that. In another recent case, one of extensive lymphosarcoma of the abdomen and pelvis, a cure had been effected in ten days.

Dr. Francis Carter Wood, director of Cancer Research, Columbia University, said that the position which he took in regard to this matter was one somewhat between the enthusiasm of Doctor Kelly and the moderation of some of the more conservative authorities. All that he wished to do on this occasion was to make a plea for the utmost care and caution in announcing results. In all cases thorough microscopical studies should be made, to establish the diagnosis, and a reasonable time permitted to elapse before reporting a cure. He was seeing cases of cancer of the breast in which there had been recurrence after twelve years. Cancer was not an easy thing to cure, and it was only right that one should wait at least six years before announcing a cure. Personally, he knew that some of the cases alleged to have been cured by radium were not cured. The whole question of cancer was as yet an unsettled one.

Dr. Willy Meyer stated that the statistics which Doctor Levin had shown in his chart were not up to date. Thus, in cancer of the esophagus the chart gave 100 per cent. as the primary operative mortality, while, as a matter of fact, two successful operations had been reported, one by Doctor Torek, of New York, and one in Europe. One reason why the mortality had been so great was that it had been only within the last twelve months that they had learned how to operate. It was now known that a gastrostomy must first be done, for otherwise both pneumogastrics would be divided. Cancer of the cardium was also now within the field of operative surgery. He was glad to hear that those speaking on the use of radium had advocated operation first and radium applications afterward. It would be a great mistake, on account of the widespread campaign which had been inaugurated, to impress the public with the vital importance of early diagnosis and early operation, to have the idea go out that radiotherapy could be substituted for surgical interference. In its proper place radium was undoubtedly a very useful agent, but one serious objection was its enormous expense. The
gamma rays from radium were very similar to the Röntgen rays, and, from the most recent developments in regard to the latter, he believed that the time would come when they would be able to substitute the hard tube Röntgen rays for radium in all cases where the use of this agent was now called for.

Dr. Abraham Jacobi said that personally he presented an instance of a cure effected by radium. Seven years ago an epithelium appeared upon his nose, and for about two years it gave him a great amount of worry. He was then subjected to radium treatment, and a prompt cure resulted. This was accomplished by three applications one of three minutes, one of four minutes, and one of seven minutes—at short intervals.

Dr. Louis J. Lajinsky said that until recently the results of operations for cancer of the uterus had been most discouraging, but since the plan of applying radium after the operation had been introduced, gynecologists were inspired with new hope.

Elective of Officers.—The following officers were elected for the ensuing year: President, Dr. Joseph Bieber; first vice-president, Dr. I. Strauss; second vice-president, Dr. M. Keschner; recording secretary, Dr. Samuel J. Scadron; corresponding secretary, Dr. Harry E. Isaacs; treasurer, Dr. Herman Lober; trustee for three years, Dr. Joseph Barsky.

Book Reviews.

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

The Practice of Medicine, A Textbook for Practitioners and Students with Special Reference to Diagnosis and Treatment. By James Tyson, M.D., LL.D., Emeritus Professor of Medicine in the University of Pennsylvania and Formerly Physician to the Hospital of the University, etc., and M. Howard PusSELL, M.D., Professor of Applied Therapeutics in the University of Pennsylvania physician to the hospital of the University, etc. Sixth Edition, Revised and Rewritten. With Six Plates and 179 Illustrations. Philadelphia: P. Blakiston's Son & Co., 1913. Pp. xvi-1211. (Price, $3.50.)

All those who know Professor M. Howard PusSELL will give due praise to Professor Tyson for his selection of an associate so eminently able as a therapistic to aid him in the preparation of the sixth edition of his textbook. The phrase, new edition, means little to the reviewer today; a few additions here and there attesting to the paucity of labor devoted by the author to the literature of the various subjects: a cursory perusal of two or three recently published works and a few new hints derived therefrom seem quite sufficient to serve the authors. This cannot be said of Tyson's practice. Carefully selected additions to the various diseases treated are numerous, while among the diseases introduced for the first time in the work may be mentioned: Diseases of the pituitary gland, trypanosomiasis, Roseola, mumps, rosette, diverticulosis, bacteria in the appendix, melanoma, oxaluria, phosphaturia, indigincuria, cystinuria, erythema, diseases of the thymus gland, hypertrophy and hyperthyroidism, hypertrophic pulmonary artery, Osteitis deformans, Leontiasis ossea, Osteogenesis imperfecta, osteoathrosis and osteophyly.

This work is a valuable addition to the textbooks on hygiene and sanitation and covers a larger field than any other available. This is a feature of various importance to those who, in increasing numbers, are beginning to adopt hygiene as a specialty, also to the many physicians who are connected with municipal sanitation. The prolonged connection of Doctor Rosenau with the Public Health Service has enabled him to gather a great deal of practical experience which is reflected in the present work. The first part includes the prevention of preventable diseases, venereal prophylaxis, heredity, immunity, and eugenics, i.e., subjects dealing with the body proper; while the second part deals with the environment in its relation to disease. The style is clear and not burdened with ultrascientific terms and is, therefore, quite within the reach of the general practitioner.

This volume contains an extensive presentation of the large amount of work that the authors have done in their successful attempts to split up proteins into two main groups, the poisonous and the nonpoisonous. The basic principle of their work is stated in the following paragraph taken from the preface. "The keystone or archon of the protein molecule is our poison. It is common to all protein molecules. It is the primary group. One protein differs from another in the secondary and tertiary groups. Ordinary proteins are not poisonous, because in them the chemism of the primary group is satisfied by combination with secondary groups. Strip off the secondary groups and the primary becomes poisonous on account of the avidity with which it combines with other "secondary group."" Discussing the tubercle bacillus an important point brought out is the fact that tuberculin does not sensitize or does so imperfectly. Consequently there is raised a serious question as to its employment as a therapeutic agent. The chapter on protein sensitization or anaphylaxis is extremely valuable in that it gives this complicated subject a very careful and clear review. This book is a most important one and should be studied thoroughly, both by the laboratory worker and the practitioner who is interested in knowing the underlying factors of the manifestations of disease.

Essentials of Pathological Chemistry. Including Description of the Chemical Methods Employed in Medical Diagnosis. By Victor C. Myers, M. A., Ph. D., Professor of Pathological Chemistry, New York Postgraduate Medical School and Hospital who is In charge of the Laboratory; and J. A. Ph. D., Instructor in Pathological Chemistry, New York Postgraduate Medical School and Hospital. New York: Reprinted from the Postgraduate, 1913. Pp. v-137. (Price, $1.25.)

This volume consists of individual chapters designed primarily as a guide for classes in elementary pathological chemistry. In order that the pathological processes be properly understood the normal physiological functions are first presented. Inasmuch as this work is the result of actual experience in laboratory teaching, it is very well adapted for its particular purpose. The various reactions are given in minute detail so that there can be no misunderstanding. In an appendix the authors give some valuable suggestions as to the necessary apparatus in outfitting a laboratory and the forms of blanks used for examinations of the urine, feaces, and gastric contents. This book can be well recommended.
Interclinical Notes.

It is now announced that man’s friend and companion, *Cimex lectularius*, is a carrier of tuberculosis. Whence came this knowledge? Alas, we know only too well and we trust that such news will in future, if too it is too late, ascertain what soulless experimenters are tearing and crushing and tearing this affectionate little bed-fellow of the poor man, and write letters to their accredited organ. *Life*, with the usual sublime attacks on the medical profession. Only a hardened brute can ponder with indifference the idea of a tiny insect, not only helpless, but sick of a dreadful disease, subjected to the tortures of the heavy steel racks and red hot irons of the anti-imagination, instead of being permitted peaceably to cough its little life away. It is hard to conceive a more pathetic picture than that of a row of bedbugs facing the relentless chief of staff and meditating on unison *Moritur et saltamus*.

Meetings of Local Medical Societies.

**FRIDAY, January 2d.—** New York Academy of Medicine (Section in Surgery); New York Microscopical Society; Gynecological Society of Brooklyn; Manhattan Dermatological Society; Practitioners’ Society of New York; Corning Medical Association; Saratoga Springs Medical Society.

**Official News.**

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending December 17, 1913:

**Bogges, J. S., Surgeon.** Granted one month’s leave of absence from January 1, 1914. **Bolton, Joseph, Assistant Surgeon.** Directed to report to Surgeon Joseph Goldberger for duty in connection with investigations of an outbreak of diphtheria. **Goldberger, J., Surgeon.** Directed to proceed via Philadelphia, Pa., to Detroit, Mich., and make a detailed investigation of the origin and prevalence of diphtheria in the latter city. **Kerr, J. W., Assistant Surgeon General.** Reassigned to duty in the Bureau as Assistant Surgeon General in charge of the division of scientific research, effective December 18, 1913. **Olesen, Robert, Passed Assistant Surgeon.** Reassigned, instead of duty at the San Francisco quarantine station, Angel Island, Cal., and directed to report to the director of the Hygienic Laboratory for temporary duty, effective December 15, 1913. **Safford, M. Victor, Assistant Surgeon.** Granted one month’s leave of absence from November 27, 1913, on account of sickness. **Treadway, W. L., Assistant Surgeon.** Detailed as a member of a board for the preparation of a manual for the mental examination of immigrants, vice Acting Assistant Surgeon Gheuck, resigned. **White, J. H., Surgeon.** Reassigned to duty at the Marine Hospital, New Orleans, La., effective December 1, 1913. **Wille, C. W., Surgeon.** Directed to proceed to Cincinnati, Ohio, to inaugurate and carry out an investigation of tuberculosis in relation to the manufacturing industries. **Williams, C. L., Assistant Surgeon.** Directed to proceed to Detroit, Mich., and report to Surgeon Joseph Goldberger for duty in connection with investigations of an outbreak of diphtheria. **United States Army Intelligence:**

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Army for the week ending December 20, 1913:

**Brown, Ira C., First Lieutenant, Medical Reserve Corps.** Relieved from duty in the Medical Reserve Corps and will proceed to his home. **Capan, Nelson, First Lieutenant, Medical Corps.** Will proceed to the Walter Reed General Hospital, Takoma Park, D. C., for observation and treatment. **Duncan, Louis C., First Lieutenant, Medical Corps.** Granted leave of absence for ten days. **Holland, J. H., First Lieutenant, Medical Corps.** Resignation accepted, effective March 1, 1914; granted leave of absence from date of arrival in the United States to May 1, 1914.

So much of paragraph 28, Special Orders No. 275, November 24, 1913, War Department, as directs First Lieutenant Harry G. Ford, Medical Corps, to report for his examination on January 12, 1914, is amended so as to permit him to report, as Second Lieutenant Colonel Henry C. Fisher, Medical Corps, president of the examining board in Washington, D. C., as soon as practicable after the return of First Lieutenant George E. Parisoud, Medical Corps, to the Canal Zone.

**Births, Marriages, and Deaths.**

**Married.**

**Aisenstadt—Terrell.**—In Chicago, on Tuesday, December 9th, Dr. Albert E. Aisenstadt and Miss Ethel Terrell. **Burrus—Dobson.**—In Statesville, N. C., on Tuesday, December 2d, Dr. M. V. Burrus, of Nebraska, and Miss Ruth E. Dobson, of Statesville, N. C. **Conner—Schwanebeck.**—In Baltimore, Md., on Wednesday, December 17th, Dr. John B. Conner, and Miss Marie A. Schwanbeck. **Tisdale—Long.**—In Minneapolis, Minn., on Wednesday, December 10th, Dr. William Long, and Miss Mary Vail Tisdale. **Cole.**—In Roxboro, N. C., on Wednesday, December 3d, Dr. B. E. Love and Miss Julia Cole.

**Died.**

**Agnew.**—In Paterson, N. J., on Tuesday, December 16th, Dr. Frank Edward Agnew, aged fifty years. **Bartram.**—In Newburgh, N. Y., on Wednesday, December 17th, Dr. W. C. Bartram, aged thirty-four years. **Cecil.**—In Louisville, Ky., on Friday, December 12th, Dr. John G. Cecil, aged fifty years. **Comer.**—In Cleves, Ohio, on Sunday, December 8th, Dr. William Colby Cooper, aged seventy-eight years. **Darden.**—In Norwood, Ga., on Thursday, December 4th, Dr. N. M. Darden, aged fifty-five years. **Dienefbach.**—In Newark, N. J., on Wednesday, December 21st, G. P. Dienefbach, aged sixty-two years. **Dorset.**—In Bonham, Texas, on Sunday, December 7th, Dr. J. S. Dorset, aged eighty years. **Durrett.**—In Louisville, Ky., on Saturday, December 13th, Dr. W. T. Durrett. **Gaston.**—In Collfax, La., on Tuesday, December 13th, B. T. Gadd, of Mitchellville, aged eighty years. **Hackenbach.**—In Chicago, Ill., on Tuesday, December 4th, Dr. John A. Hackenbach, aged eighty-two years. **Haggeman.**—In Mobile, Ala., on Tuesday, December 9th, Dr. Frederick C. Haggeman, aged ninety-nine years. **Hall.**—In Mountain Creek, Ala., on Friday, December 5th, Dr. A. J. Hall. **Judsons.**—In Columbus, Ohio, on Tuesday, December 9th, Dr. William Judson, of Statesville, aged fifty-five years. **Key.**—In Monroe, La., on Sunday, December 7th, Dr. H. -Key. **McInerney.**—In Pittsburgh, Pa., on Tuesday, December 9th, Dr. John McInerney, aged sixty-eight years. **Parks.**—In Columbus, Ohio, on Saturday, December 13th, Dr. R. E. Parks, of Elyria, Ohio. **Stoddler.**—In Hillsdale, Me., on Sunday, December 7th, Dr. O. P. S. Stoddler, aged seventy-seven years. **Soulé.**—In Boston, Mass., on Wednesday, December 10th, Dr. John Albion Soulé, aged seventy-two years. **Stoddler.**—In Marshfield, Mass., on Friday, December 12th, Dr. C. W. Stoddler, aged forty-eight years. **Ward.**—In Long Beach, Cal., on Saturday, December 6th, Dr. W. H. Ward. **Wheeler.**—In Washington, D. C., on Monday, December 15th, Dr. Myron W. Wheeler, United States Navy, aged thirty-nine years. **Wood.**—In Antwerp, N. Y., on Thursday, December 18th, Dr. Gary Wood, aged fifty-nine years.
LIST OF ILLUSTRATIONS TO VOLUME XCVIII.

Adhesions and intestinal angulations in relation to chronic constipation. Eleven Illustrations ........................................ 5-10
Amino nitrogen content of sera. One Illustration ....................... 159
Apparatus for proctolysis. Two Illustrations ................................ 1023
Appendix, differential diagnosis of, by x ray. Eighteen Illustrations ... 697-704
Arthritis of hip. One Illustration ........................................... 615
Arteriometer. Three Illustrations ............................................ 1016
Bladder, topography of. Four Illustrations ................................ 355-356
Blood letting apparatus. One Illustration .................................. 966
Bursitis, retrocalcanean. Four Illustrations ................................. 265-266
Cannula, curved. One Illustration ............................................ 81
Cervix, movements of two halves of, in disease. Eleven Illustrations ... 705-708
Cystoscope and evacuator, combined. Two Illustrations .................. 285
Diabetes mellitus treated with Bacillus bulgaricus. Five Illustrations . . 797-802
Drainage for suprapubic prostatectomy. One Illustration ................. 416
Drainage tubes for nares. Two Illustrations ................................ 472
Duodenal instruments. Ten Illustrations ..................................... 751-755
Dysentery in tropics. Three Illustrations ................................... 258-266
Epilepsy. One Illustration ................................................... 1199
Epithelioma of lower lip in a woman. Two Illustrations .................. 617
Fracture of pelvis in a child. One Illustration ............................... 908
Gastrointestinal symptoms. Eight Illustrations .............................. 359-365
Imbeciles, test for. Two Illustrations ....................................... 1015
Intestinal obstruction due to pelvic tumor. One Illustration ............. 1163
Jaundice in children. Two Illustrations ..................................... 261
Kinetic neuroses and psychoses. Two Illustrations ......................... 1163
Labyrinth, inflammatory affections of. One Illustration .................. 213
Leprosy in a negro. One Illustration ........................................ 708
Leprosy, surgical cure of. Three Illustrations ....... 265-266
McBurney, Charles. Portrait ................................................... 978
Moronism and ignorance. Four illustrations ................................. 154-156
Orbital abscess. One Illustration ............................................ 1195
Orthopedics in general practice. Thirteen Illustrations .................. 451-452
Osteoarthropathy, hypertrophic pulmonary. Two Illustrations .......... 609-610
Paralysis, infantile, affecting lower extremities. Ten Illustrations ... 908-912
Pharyngoscope. One Illustration ............................................ 615
Pneumothorax, induced. Eight Illustrations ................................. 899-905
Position of stomach in relation to posture. Thirty Illustrations .. 551-556
Roosevelt Hospital, Doctor McBurney operating in. One Illustration .... 979
San Diego, Cal. Five Illustrations ........................................... 559-562
School children, health of. Four Illustrations ............................... 795
Servian-Bulgarian war, surgical experiences during. Five Illustrations . 906-907
Sphygomonometer. One Illustration ........................................ 220
Spina bifida. Eight Illustrations ........................................... 1159
Tests in relation to eyes. One Illustration ................................ 256
Testicular extract, action of. Twelve Illustrations ......................... 2-3
Tests for detection of defectives. Six Illustrations ....................... 542
Vaccine treatment of typhoid fever. Eight Illustrations .................. 453
Wassermann reactions. Two Illustrations ................................... 1012
X rays diagnosis of diseases of chest and abdomen. Seven Illustrations . 661-668
X rays in diseases of chest and abdomen. Five Illustrations ............. 708
